Essays on Trade Openness and Vulnerability to Poverty

PIERLUIGI MONTALBANO

Thesis submitted for the examination of Doctor of Philosophy

University of Sussex, UK
June 2016

Acknowledgements:

This work is dedicated to my family and especially to Silvia, my companion both in work and daily life.

Main main debt is to L. Alan Winters for his invaluable support and guidance.

A special thank goes to Umberto Triulzi who encouraged and supported me in undertaking this new challenge. I am also grateful to ZhenKun Wang, Andy McKay, the PhD students and all the members of the Department of Economics at the University of Sussex that kindly supported me during the entire research program.

I would like also to thank all the participants in the following Seminars and Conferences where previous versions of various bits of this work have been presented: The DIAL International Conference held in Paris, 30th June - 1st July , 2011; The Departmental Seminar held in Falmer (UK), Department of Economics, University of Sussex, 7th March 2012; The Scottish Economic Society annual Conference held in Perth, 16th-18th April, 2012; The 53th Italian Economic Society Annual Conference, Universita' della Basilicata, Matera (Italy), 19th October 2012.

The usual disclaimers apply.

SUMMARY

This thesis focuses on the welfare costs of exposure to risk linked to openness to international trade. This is a prominent issue in international debate, whereas it is largely ignored by trade literature, both theoretical and empirical. Trade theory is mainly focused on the first moment of the above relationship, which is actually insufficient for welfare purposes when people are risk averse. Empirical evidence is mixed, scattered in separate fields of analysis, and does not reach a common stance. As a result, current literature fails to make a full assessment of the net welfare impact of an opening-up process.

This work contributes to the above debate by proposing:

- A comprehensive review of the literature on the “destabilising effects” of openness to international trade;
- An empirical test on the significance and relevance of “precautionary saving” behaviour under risk, estimated from cross-country data;
- A conceptualisation of vulnerability to poverty induced by trade openness;
- A comprehensive analysis of vulnerability to poverty induced by trade liberalisation in Vietnam under Doi Moi,¹ by exploiting the available household living standard surveys for the period 1992-2008;
- An extended version of Ligon and Schechter’s (2003) measure of Vulnerability as low Expected Utility;
- An empirical application of the adjusted VEU measure to “trade-induced vulnerability” using VHLSS panel data (2002-06)

The work is divided into four essays as follows:

1. Review of the literature and conceptualisation (and misconceptions) of “trade-induced vulnerability to poverty” (Essay 1);
2. A cross-country empirical test in the long-run behaviour of consumption under risk (Essay 2);
3. A cross-sectional empirical test of trade-induced vulnerability in Vietnam under *Doi Moi* (period 1992-2008) (Essay 3);
4. A panel empirical test of trade-induced vulnerability in Vietnam in the period 2002-06 (Essay 4).

¹“Doi Moi” (renovation) was a comprehensive process of reforms undertaken from the early 1990s by Vietnam characterised by a combination of liberalisation, stabilisation and structural reforms.

Introduction

This thesis focuses on the welfare costs of exposure to risk linked to openness to international trade. This is a prominent issue in international debate, whereas it is largely ignored by trade literature, both theoretical and empirical. Trade theory is mainly focused on the first moment of the above relationship which is actually insufficient for welfare purposes when people are risk averse. Empirical evidence is mixed, scattered in separate fields of analysis, and does not reach a common stance. As a result, current literature fails to make a full assessment of the net welfare impact of the opening-up process.

In principle, trade can alter risk exposure in two ways: by changing the riskiness of existing activities, for instance, by altering the weight of foreign compared with domestic shocks faced by the economy, or by changing the emphasis among the different activities households engage in such as, for example, switching from subsistence food crops to cash crops (McCulloch et al., 2001).

According to the theory of precautionary saving (Kimball, 1990; Caballero, 1990; Deaton, 1992; Carroll 2001a; Carroll & Kimball, 2008), risk-averse people react to risk by modifying their behaviour, and more specifically, by undertaking additional saving and reducing current consumption. This implies a smooth path of consumption that is lower than if the same average income were available with certainty which implies permanent negative effects on welfare. This is particularly true for people characterised by a poor ability to take advantage of the positive opportunities linked to trade reforms and weak mitigating strategies. In the midst of trade reform, they carry out extra/unproductive saving and follow conservative choices shying away from profitable but risky investments (Winters et al., 2004). This is the innermost source of vulnerability induced by trade. It is neither directly observable nor linked to the actual manifestation of shocks. Moreover, it also implies that mean consumption reflects the negative impact of risks. Thus, mean consumption cannot be used as a riskless counterfactual as is implicitly done by current vulnerability measures. As a result, current vulnerability measures

tend to underestimate the overall impact of risk on consumption, leading to biased (downward) estimates of the overall effect of risk on welfare.

This work contributes to the above debate by proposing:

- A comprehensive review of the literature on the “destabilising effects” of openness to international trade;
- An empirical test on the significance and relevance of “precautionary saving” behaviour under risk, estimated from cross-country data;
- A conceptualisation of vulnerability to poverty induced by trade openness;
- A comprehensive analysis of vulnerability to poverty induced by trade liberalisation in Vietnam under Doi Moi,² by exploiting the available household living standard surveys for the period 1992-2008;
- An extended version of Ligon and Schechter’s (2003) measure of Vulnerability as low Expected Utility;
- An empirical application of the adjusted VEU measure to “trade-induced vulnerability” using VHLSS panel data (2002-06)

The added value of this work is twofold:

- it detects the relevance of precautionary saving under risk at both cross-country and household levels;
- it proposes a novel empirical approach to looking at trade-induced vulnerability by separating the *ex-ante* effects of risk from the *ex-post* effects of shocks.

The presentation of the overall work is divided into four essays as follows:

1. Review of the literature and conceptualisation (and misconceptions) of “trade-induced vulnerability” (Essay 1);
2. A cross-country empirical test in the long-run behaviour of consumption under risk (Essay 2);
3. A cross-sectional empirical test of trade-induced vulnerability in Vietnam under *Doi Moi* (period 1992-2008) (Essay 3);

²*Doi Moi* (renovation) was a comprehensive process of reforms undertaken from the early 1990s by Vietnam characterised by a combination of liberalisation, stabilisation and structural reforms.

-
4. A panel empirical test of trade-induced vulnerability in Vietnam in the period 2002-06 (Essay 4).

The first challenge to undertake was to bridge trade openness and vulnerability to poverty which are traditionally seen as separate topics by the specialised literature. While the debate over trade openness and its measurement has been extensively investigated since Krueger's (1978) seminal work, vulnerability assessment is still at the "let a hundred flowers bloom" stage, as stated by Hoddinott and Quisumbing (2003). On the trade side, this work relies on the operational definition of "openness in practice", regardless of whether or not this depends mainly on deliberate policies (for a clear distinction between the two concepts, see McCulloch et al., 2001). Furthermore, it does not distinguish, at this stage, between the various sources of economic fluctuation linked to trade openness (price fluctuations, exchange rate volatility, policy mismanagement, etc.). The added value of this piece of work is to complement the literature that emphasises the risk side of trade reform and its impact on households' optimal portfolios, especially for the poor (Winters, 2002; Winters et al., 2004) with the literature on vulnerability to poverty able to measure the net welfare cost under risk. Since the most popular vulnerability measures based on expected values of the common Foster-Greer-Thorbecke (FGT) class of decomposable poverty measures (the so-called Vulnerability as Expected Poverty - VEP measures) are based on a weak theoretical background (Chaudhuri, 2001, 2003; Chaudhuri & al., 2002; Christiaensen & Boisvert, 2000; Christiaensen Subbarao, 2001; Gunther Harttgen, 2009; Pritchett et al., 2000), Ligon and Schechter's (2003) Vulnerability as low Expected Utility (VEU) measure has been taken as the main empirical reference of vulnerability induced by trade openness. It is micro founded, empirically based and presents some clear advantages over other groups of micro-founded vulnerability measures, e.g., the class of Vulnerability measures looking at the Threat of Poverty (VTP) (Calvo and Dercon, 2013; Povel, 2015, Chaudhuri & al., 2002; Kamanou & Morduch, 2004; Pritchett & al., 2000; Dutta et al., 2011; Gunther & Maier, 2008).

A key distinction to bear in mind in this work is between risk and shock. Current measures of vulnerability to poverty show a structural inability to provide separate assessments of the *ex-ante* impacts on welfare of both risk and risk-mitigating strategies from the *ex-post* impacts of shocks and their related coping strategies. Thus, they fail to properly address vulnerability. For instance, a household adopting *ex-ante* a complete self-insurance mechanism at the cost of lower mean consumption would be registered as being unaffected by risk, producing a structural underestimation of the risk component of vulnerability with a parallel overestimation of its poverty component,

leading to biased outcomes (Elbers and Gunning, 2003). These authors also show that much of the effect on household expected consumption reflects *ex-ante* risk. This is particularly important in trade analysis where the risk component, as above noted, is virtually absent in the current debate on the net welfare impacts of trade reforms, theoretical and applied.³

The issue of properly addressing the impact of *ex-ante* risk on vulnerability has been generally performed by deriving simulation-based estimates of vulnerability grounded on structural dynamic models of household consumption and saving, modelled as the outcome of intertemporal optimisation under uncertainty (see, among others, Elbers and Gunning, 2003; Elbers et al., 2007; Elbers et al., 2009; Carter and Ikegami, 2009). Since we lack general agreement on what the right dynamic model is for any given economic environment in which vulnerable households actually live, the current work follows the strand of the literature that argues that it is more fruitful to derive empirically-based analyses of vulnerability, focusing on Euler-type restrictions on the evolution of the household consumption over time. Specifically, since households do their best to smooth consumption over dates and states of the world, this literature claims that the Euler restrictions can be exploited to estimate “*ex-ante*” measures of vulnerability even in the absence of a fully specified dynamic model (Ligon, 2011). Consumption smoothing behaviour is also consistent with the standard hypothesis of the stationarity of consumption over time and states that characterises current applied vulnerability measures, even when the distribution of individual income is not stationary. Looking primarily at consumption behaviour also looks reasonable for the following reasons: i) it is consistent with the standard empirical literature that looks at consumption as a more reliable indicator of individual welfare than income; ii) it is consistent with the specific situation of poorer households, which traditionally have few assets and are credit constrained with important knock-on effects on their ability to smooth consumption (McCulloch et al., 2001) and, iii) it acknowledges that consumption choices actually engender a further set of behavioural changes that are likely to produce effects on household welfare such as: smoothing asset/income; self-insurance; risk-sharing arrangements; diversification, multiple occupations, migration, etc. (Morduch, 1994; Rosenzweig and Wolpin, 1993; Townsend, 1994; 1995, Carter and Barret, 2006; Zimmerman and Carter, 2003). However, this

³The only reference to vulnerability in trade policy is related to the *ex-post* status of developing countries in terms of remoteness (in the case of Small Island Development States, SIDS), and lack of diversification of exports (for the eligibility to the GSP+ schema of the European Union). Additional details can be found in Winters & Martins (2004); Briguglio, 1995; Briguglio et al., 2009; Briguglio & Galea (2003); Guillaumont, 2009 and 2010).

choice stands on the implicit assumption that consumption behaviour is the key behavioural variable in explaining household choices under risk.

This work contains a conceptual part and a set of empirical applications: since panel data are ideal for testing the theory of consumption but scarce at the micro level, a first cross-country empirical exercise was carried out to test the relevance and significance of the “extra-saving” hypothesis in response to macro-fluctuations in income. Then, two empirical assessments of trade-induced vulnerability were carried out at the household level. The latter are focused on Vietnam and take advantage of the available household living standard surveys covering the period 1992-2008.

The choice of Vietnam as the primary case study for the household level empirical analysis is not casual. The reason is threefold: i) since the early 1990s, Vietnam undertook a vast process of reforms, namely the *Doi Moi* (renovation), a combination of liberalisation, stabilisation and structural reforms, that determined a sudden opening up to international market of a previous planned economy; ii) empirical analyses consistently highlight the increased importance of international trade on Vietnamese economy as well as the positive empirical correlation between trade liberalisation and poverty reduction; iii) we can benefit from a collection of six household living standard surveys for the full period 1992-2008. The challenge was to complement the existing empirical evidence on the relationship between trade openness and poverty in Vietnam under *Doi Moi* with a parallel empirical analysis of the relationship between trade openness and vulnerability to poverty. Following on from Winters (2002) who provides an overall picture of the transmission channels between trade and poverty, this work assesses vulnerability induced by trade by relying on a workable empirical identification strategy which focuses on the presence of behavioural heterogeneity in consumption across households clustered by industries characterised by different degrees of trade exposure. The assumption is that the presence of heterogeneity in vulnerability scores across clusters of households classified by trade exposure strongly suggests heterogeneity in their risk exposure and/or mitigating strategy with significant policy implications.

As already noted, the thesis is divided into four essays.

The first essay presents a comprehensive review of the literature on the destabilising effects of trade openness, drawing together studies in different fields. It also provides a conceptualisation (and discusses the most common misconceptions) of vulnerability induced by trade openness and the main lines of direction for research on the link between trade openness and vulnerability to poverty. It highlights, on the one hand, the extent of the very informative work currently available on the topic and, on the other hand, the urgent need for more focused work on the implications of trade openness in

terms of vulnerability. This piece of work first introduces the separate concepts of economic fluctuations, risk and uncertainty and their actual implications for welfare in developing countries, and then investigates the possible channels of transmission between trade openness and economic instability.

The second essay is a comprehensive empirical test of the significance and relevance of consumption smoothing under permanent risk. It presents conservative (i.e., lower bound) estimates of the relation between permanent risk and consumption smoothing based on a long (pre-crisis) cross-country panel setting (1950-2008). It proposes both LSDV and system GMM estimates of an ARDL model of consumption behaviour under risk based on the maximisation of the expected value of a time-separable CARA utility function over an infinite horizon (see Blanchard and Fischer (1989), Caballero (1990 and 1991), Weil (1990), Guiso et al., (1992) among others). As suggested by Carroll and Samwick (1997), Reis (2009) and Krebs et al. (2010), the permanent component of *ex-ante* income risk was filtered out as a measure of permanent risk. The reason is twofold: i) to let the transitory component of income risk absorb the measurement errors, leading to unbiased estimates of *ex-ante* risk; ii) to acknowledge that the more persistent the effect of the stochastic component of income is, the larger its impacts via the standard precautionary savings channel are assumed to be since permanent effects cannot easily be insured by smoothing consumption (for a thorough analysis of the issue of persistence, see Reis, 2009). While it focuses only on aggregate risks and rests on the implicit assumption that incomes are perfectly pooled across individuals (i.e., a representative agent hypothesis), it goes beyond averages and controls for country heterogeneity also providing estimates by income deciles. The main innovation to the existing literature in this first empirical exercise lies in proposing a way to look empirically at the cost of volatility on welfare that is alternative to using compensation parameters of household preference for stability (see, for instance, Lucas, 1987, 2003 and Reis, 2009). More specifically, this essay focuses on the impact of risk on current and future consumption possibilities (and welfare) which implies relative changes in portfolio allocation between risky capital and safe assets (Loayza et al., 2007; Reis, 2009; Cherif and Hasanov, 2012).

The third essay presents - to the best of my knowledge - the first comprehensive analysis of vulnerability to poverty induced by trade liberalisation in Vietnam under *Doi Moi* for the entire period 1992-2008, by exploiting all the available household living standard surveys. First of all, it presents an empirical assessment of Vulnerability to Poverty (VEP) induced by trade openness. Thus, acknowledging the structural limitations of VEP in further decomposing its risk-induced component, it also presents “upper bound” estimates on the relative importance of the various determinants of consumption

behaviour under risk, by distinguishing the relative influence of *ex-ante* and *ex-post* factors. Finally, by clustering households by trade-related industries, it also presents some informative analyses across trade clusters of the heterogeneity in their stochastic component of income innovation (i.e., the component of income variation unexplained by observables). The striking feature of this first empirical exercise lies in highlighting the non-decreasing importance of the share of the vulnerability component of consumption behaviour linked to the stochastic determinants and/or *ex-post* shocks - an issue traditionally overlooked by the empirical literature in the field. Moreover, these estimates show that risk exposure varies systematically with the trade exposure of surveyed households.

The fourth essay proposes an extended version of Ligon and Schechter's (2003) VEU measure of vulnerability that is able to control for trade-related heterogeneity in households' exposure to shocks. Moreover, it also overcomes the common weakness of currently available measures of vulnerability, i.e., the inability to decompose the *ex-ante* impact of risk and its correlated risk-mitigating strategies from the *ex-post* ones. To provide an empirical application of this extended VEU measure, the essay focuses on VHLSS panel data (2002-06) and follows three methodological steps: first, following Ligon's (2006) approach, the VEU measure was further decomposed by filtering out a trade-related risk component from the aggregate component of risk premium able to capture any systematic variation in the expected level of log consumption across households classified by trade clusters. More specifically, it is argued that, because of heterogeneity in trade exposure between tradable and non-tradable industries, global risks do not affect households homogeneously and the residuals show up a systematic correlation across households clustered in industries characterised by the same degree of trade exposure. Second, as suggested by several authors (Elbers and Gunning 2003, Elbers et al. 2007, Elbers et al. 2009, Carter and Ikegami, 2009), with regard to the assumption that households correctly perceive the distribution of risk they face even when they actually do not experience any shock, the idiosyncratic component of the VEU measure is further decomposed by filtering out an idiosyncratic *ex-ante* component of risk. This lets us separate the cost of risk due to the *ex-ante* change in consumption behaviour from the other components of the risk premium and so give a distinct value to the costs of mitigation strategies compared with *ex-post* coping ones. Third, once again, the persistent component of *ex-ante* risk is further filtered out. This makes the extended version of VEU fully consistent with the theoretical and empirical prediction that a rational consumer safeguards against future bad shocks by reducing current consumption and over-accumulating saving in safe (unproductive) assets (Caballero 1990, Deaton 1992, Carroll 2001a). To test the

significance of the separate impacts of the *ex-ante* permanent risk on both non-random consumption and on the risk premium, the correlates between permanent risk and the various components of trade-induced vulnerability are also presented. Finally, to control for the presence of heterogeneity in vulnerability scores by trade-related sectors, the VEU outcomes and the various components of the risk premia are calculated for cohorts of households defined by the degree of trade exposure of the industry from which they earn their main incomes.

Chapter 1

Essay 1 - Review of the literature, conceptualisation (and misconceptions) of trade-induced vulnerability to poverty

This essay introduces the reader to the welfare costs of exposure to shocks and uncertainty linked to trade openness - a prominent issue in international debate. It presents, first, a comprehensive review of the literature on the “destabilizing effects” of trade openness, drawing together studies in different fields. It thus provides a conceptualisation of trade-induced vulnerability and the promising lines of reasoning for future research on the link between trade and vulnerability.

Keywords: vulnerability, trade openness, volatility, crisis transmission, developing countries.

JEL: F10; F40; I32; E17, D60, O10

1.1 Introduction

According to theory, international trade improves resource allocation, lowers prices for consumers and leads to a more efficient production. An open trade regime also encourages the integration of the economy into the

global system and imports of modern technology, which results in productivity improvements. Accordingly, international organizations advocate policy reforms centred on trade liberalization to foster growth and welfare.

However, a key issue remains unanswered: does trade openness magnify exposure to foreign shocks raising uncertainty and, eventually, producing long term effects on partner countries welfare? This topic is currently hotly debated by practitioners, whereas it is largely ignored by trade literature. Trade theory does not provide a full understanding of the links between trade openness, shocks and uncertainty. Empirical evidence is mixed, scattered in separate fields of analysis and does not reach a common stance. A number of attempts have been carried out recently to investigate more carefully this issue both at the aggregate (Montalbano & al., 2006, 2008; Guillaumont, 2009, 2010; Naude & al., 2009a),¹ and at the households level (Winters, 2002; Winters & al., 2004). However, these pioneer works lack consistency in terms of conceptualisation and methods.

This work aims at contributing to the above debate by providing a comprehensive conceptualisation of “trade-induced vulnerability” and some directions for future research on this topic at different levels of investigations (macro, micro and meso).

A first challenge is to bridge two relevant issues, traditionally seen as separate topics: trade openness and vulnerability. While the debate around trade openness and its measurement has been extensively investigated since Krueger (1978) seminal work, vulnerability assessment is still at the “let a hundred flowers bloom” stage, as stated by Hoddinott and Quisumbing (2003) and there are several misconceptions related to its analysis. The main focus of this work is the vulnerability analysis of the effects of trade openness on partner countries. Specifically, this essay addresses the issue of whether or not, and eventually under which conditions, trade openness leads to increasing exposure to external shocks and/or raising uncertainty about the future on certain actors and/or specific social groups. The debate around trade openness remains indeed an important part of the story but it does not represent the main contribution of this piece of work. This essay

¹It is worth mentioning that the issue of aggregate vulnerability discussed here must be kept separated from the issue of Small Islands Developing States (SIDS) and Fragile States. SIDS are States characterized by a natural and/or endogenous inability to face external shocks (for additional details on SIDS see Montalbano & Triulzi, 2009; UNU-WIDER, 2008; Briguglio 1995; Atkins & Mazzi, 1999; Easterly & Kraay, 2000; Briguglio & Galea, 2003; Winters & Martins, 2004; Witter & al., 2002; Briguglio & al., 2009). Fragile States are countries where government does not deliver core functions to the majority of its people, including the poor. A number of post-conflict states fall into this category (UNU-WIDER 2008).

1.2 Is Trade Openness “destabilising” for developing countries?

builds on McCulloch & al.’s (2001) operational view that the relative openness of countries depends largely on the extent to which international trade determines local prices, regardless of whether or not this depends mainly on deliberate policies.²

This essay is structured as follows. Section 2 surveys the existing literature on the likely destabilizing effects of trade openness. Section 3 reviews the current theoretical and applied literature on vulnerability, presenting an overall conceptualisation of the phenomenon as well as some of the most common misconceptions. Section 4 proposes a first conceptualisation of the trade and vulnerability link and some directions for future research. Section 5 concludes.

1.2 Is Trade Openness “destabilising” for developing countries?

Most empirical work establishes a consistent and significant positive correlation between trade liberalization, growth and poverty reduction (Edwards, 1993; Frankel & Romer, 1999; Sachs & Warner, 1995; Dollar & Kraay, 2002, 2004; Cline, 2004; Winters, 2004). The drawbacks to trade openness are acknowledged basically in terms of short and medium run adjustment costs. The pervasive effects of trade openness on poverty and inequality, even in the long run, are acknowledged as well (McCulloch & al., 2001; Lundberg & Squire, 2003; Winters & al., 2004; Goldberg & Pavcnik 2004). An issue largely ignored by the above literature concerns the analysis of possible destabilizing effects of trade openness. The hypothesis of a direct link between developing countries’ instability and trade openness has several roots: i) the apparent asymmetry between the process of increasing specialisation and the presence of random, undiversifiable shocks in the export markets of open economies (Razin & Rose, 1992; Koren & Tenreyro, 2007); ii) the tendency of commodity prices which are at the core of the specialisation process in developing countries to be more volatile than those of manufacture goods (Malik & Temple, 2009); iii) the possible inconsistency between the shocks prevailing in open markets and traditional coping mechanisms and local market structures (Dercon, 2001); iv) the occurrence of boombust cycles of investment induced by trade openness in countries characterized by inadequate infrastructures and shortages of skilled labour (Razin & al. 2003); v) the role of trade liberalization in altering households’ optimal portfolios, cou-

²For a comprehensive list of standard measures of trade openness, see McCulloch & al. (2001).

1.2 Is Trade Openness “destabilising” for developing countries?

pled with greater variability in new portfolio options (Winters & al., 2004); and vi) higher risk of policy mismanagement in response to an entirely new set of incentives induced by trade openness in contexts where political institutions are weak (Gavin & Hausmann, 1996; Rodrik, 1999, Acemoglu & al., 2003, Fatás & Mihov, 2003, 2005).

Given the heterogeneity of the situations above, it is worth making explicit here: first, what is meant with “economic instability”, second, why should we care; third, what are its link with trade openness.

a. Economic instability and its long term impact on developing countries

Economic instability refers, generally speaking, to a situation of excessive fluctuations of economic variables: a phenomenon which is indeed increasing over time for a high fraction of low and middle income countries (Agenor & al., 2000; Kose & al., 2003; Wolf 2005; Loayza & al., 2007). Fluctuation is usually measured by the volatility of economic variables, proxied by the standard deviation of the first differences of observed time series (Aizenman & Pinto, 2005, Wolf, 2005).³ It reflects, empirically, the amount of uncertainty and risk of the economic variable, where risk is normally proxied by the predictable component of variability and uncertainty by its “unpredictable component”. A workable difference between risks and uncertainty has been highlighted by Knights (1921) classic work: while risk permits one to assign probabilities to the different outcomes, uncertainty normally refers to situations where several outcomes are associated with an event, but the assignment of probabilities to these outcomes may not be possible (the so called “knightsian uncertainty”). In this respect, empirical volatility can be considered more as an allied to risk in that it provides a concrete measure of the possible variation or movement of economic variables (Aizenman & Pinto, 2005). On the other hand, it has been highlighted that the volatility of economic variables is seldom predictable and, hence, total observed volatility may overestimate risk (Dehn, 2000; Aizenman & Pinto, 2005).⁴ Several applied methods have been thus put in place by the literature to extract the

³This means to assume implicitly that series have a constant trend (equal to the mean). Following the RBC literature, using business cycle filters, trend can be allowed to follow a richer, time and country dependent process, by applying the so-called “output gap” measure (Hnatkovska and Loayza, 2005).

⁴Dehn (2000), disentangling commodity prices *ex post* shocks and total volatility, demonstrates that failure to account for “predictable” changes leads to considerable overstatements of actual uncertainty. This result holds for nine definitions of uncertainty from the “simple unconditional standard deviation” to “Garchs conditional standard deviation of one step ahead forecast error dummyming out all shocks”.

1.2 Is Trade Openness “destabilising” for developing countries?

“unpredictable component” (i.e. uncertainty) from “pure risk” and sample variability (e.g., Hnatkovska & Loayza, 2005; Wolf, 2005; Demir, 2009).

It is from Lucas’ (1987) seminal work onwards that economists have dealt with the macro analysis of the “cost of fluctuations”. According to Lucas’ calculations, these costs account little in terms of welfare. This contributed to divert much of the previous attention on the issue as well as in favouring growth centred policies with respect to economic stabilization ones. However, Lucas (1987)’ results are not compatible with a number of stylized facts, e.g., the so called “equity premium puzzle” (Mehra & Prescott, 1985).⁵ Moreover, as Aizenman & Marion (1999) highlight, while risks do not necessarily do,⁶ “knightian uncertainty” produces pervasive long term effects, since agents are more reluctant to embark on new activities. Finally, from the work of Ramey & Ramey (1995) onwards,⁷ empirical cross-country studies have consistently found a negative relation between volatility, long-run growth and welfare, especially in developing economies (Aizenman & Marion, 1999; Fatas, 2000; Pallage & Robe, 2003; Kose & al. 2003; Wolf, 2005; Hnatkovska & Loayza, 2005; Demir, 2009). As Loayza & al., 2007 highlight, two are the main reasons we should care about volatility in developing countries: i) the substantial welfare loss of deviating from a smooth path of consumption, in case of consumption volatility; ii) the indirect welfare loss in terms of future consumption, in case of a negative impact of volatility on growth. Loayza & al., (2007) underline as well that developing countries not only face more volatility than industrial countries but suffer larger volatility effects, because of the intrinsic instability of the developing process (mainly linked to the weakness of their financial systems and the main characteristics of their specialisation process of production); the concrete risk of policy mismanagement (e.g., as in the case of pro-cyclical and/or erratic fiscal and monetary policies), and the presence of weaker mitigating and coping mechanisms.

b. Economic instability and trade openness: a survey of the literature

⁵The “Equity Premium Puzzle”, highlighted by Mehra and Prescott (1985) comes from the observation of higher return on equity stocks compared to government bonds. This highlight the presence of a sort of “risk premium” on equity stocks versus government bonds, i.e. individuals manifest clear risk aversion which is not compatible with standard economic models.

⁶Even when it happens and downward shocks (crises and/or “sudden stops”) occur, one is still dealing with short term episodes than could (but could not as well) produce pervasive and long term effects.

⁷At the aggregate level, volatility has been for a long time confined in standard cycle theory, mainly concerned in the decomposition of economic growth into cyclical and trend components. Thus, it has been long considered as a second-order issue in developing studies - but of primary interest in industrial countries concerned with smoothing the fluctuations of their business cycles.

1.2 Is Trade Openness “destabilising” for developing countries?

The phenomena of “trade-induced” instability have been traditionally seen as terms-of-trade shocks (Rodrick, 1998). However, open economies show, overall, greater output volatility and, in some cases, greater consumption volatility too (Hnatkovska & Loayza, 2005; Loayza & al., 2007). Winters (2002) provides a first analysis of the conditions under which foreign shocks can have specific impacts on households in developing countries, via the main transmission channels of trade openness: when foreign shocks are greater than domestic ones (e.g. when world markets are more variable than local ones); when trade liberalization affects governments’ ability to operate price stabilization policies; when trade reforms change the emphasis among the different activities engaged by households (e.g. in the case of farmers, switching from subsistence to cash crops). He concludes that international trade has a priori ambiguous implications for macro stability.

To investigate more in depth this issue, it is useful to gather current applied literature on the “destabilizing effects” of trade openness into two main strands: empirical analyses that emphasize the role of trade openness as a key determinant of aggregate volatility (Easterly & al., 1993; Mendoza, 1995; Gavin & Hausmann, 1996; Prasad & Gable, 1998; Rodrik, 1998; Kose, 2002; Kose & Yi, 2001, 2006; Wolf, 2004; Kose & al., 2005); and empirical analyses that look at trade openness as a complementary, real aspect in currency crises (Milesi-Ferretti & Razin, 1998, 2000). In this latter case, trade openness has been seen both as a means to trigger “sudden stops” (Cavallo & Frankel, 2008), or as a vehicle to spread out crises, especially in regional contexts (Glick & Rose, 1999; Easterly & Kraay, 2000; Forbes, 2002).

In both cases, empirical results are mixed. While some studies find that an increase in the degree of trade openness leads to higher volatility on a wider set of outcome variables (aggregate income, consumption, employment, salaries and prices), especially in developing countries (Karras & Song, 1996; Easterly & al., 2001; Kose & al., 2003; Di Giovanni & Levchenko, 2009; Raddatz, 2006; Loayza & Raddatz, 2007; Krishna & Levchenko, 2009; Haddad & al., 2010), others find no significant relationship between an increased degree of trade interdependence and domestic macroeconomic volatility (Calderon & al., 2005; Kose & Yi, 2006; Cavallo, 2007) or just a temporary relationship (Santos-Paulino, 2010). A separate but related issue is the role of international trade as a key determinant of business cycle transmission across countries (Anderson & al., 1999; Canova & Dellas, 1993; Clark & van Wincoop, 2001; Otto & al., 2001; Calderon & al., 2005; Calderon & al., 2007; Baxter & Kouparitsas, 2005; Imbs, 2004; Kose & Yi, 2001, 2006). This is

1.2 Is Trade Openness “destabilising” for developing countries?

consistent, theoretically, with the international “Real Business Cycle” (RBC) approach as it embodies demand and supply side spill-over channels (Stadler, 1994). However, Kose & Yi (2001, 2006), who try to match RBC and the co-movements in their empirical findings, are not able to explain its magnitude, and suggest the existence of a “trade-co-movement puzzle”.⁸

In the second strand of the literature, the role of trade openness in fostering macroeconomic crises is also hotly debated. The basic argument for a positive role of trade openness in reducing exposure to foreign shocks is that a high trade/GDP ratio helps to adjust to a cut-off in international financing. Rose (2005) provides empirical explanations for the above case, arguing that countries with higher trade/GDP ratios are less likely to default because investors are less likely to pull out, and that higher ratios of trade to GDP allow countries to cope with a cut-off of capital inflow and a smaller percentage increase in exports. Cavallo & Frankel (2008) show that trade openness makes countries less vulnerable to both severe sudden stops and currency crashes, and show that this relationship is even stronger when correcting for the endogeneity of trade, using “gravity estimates”.⁹ On the other hand, the basic argument for a pervasive role of trade openness in increasing exposure to external shocks, is grounded in the idea that a weakening export performance can trigger a sudden stop in capital flows. Furthermore, Eichengreen & Rose (1999), Glick & Rose (1999) and Forbes (2002) demonstrate empirically the role of “trade linkages” in spreading crises in regions.¹⁰ The central point here is that currency crises spread along the lines of trade linkages and, since trade patterns are strongly negatively affected by distance, - no matter who is the first victim of a speculative attack, or what factors are behind it - there is strong evidence that currency crises tend to spread regionally because of trade linkages. Forbes (2002), following Corsetti & al. (2000) and Wincoop & Yi (2000), decomposes the trade linkages of crises into three parts: i) a “competitiveness effect”, linked to changes in relative prices

⁸This new “economic puzzle” has been argued by Kose & Yi (2006) to highlight the inability of standard international business cycles models to explain the empirical findings related to the fact that pairs of countries with stronger international trade linkages tend to have more coordinated business cycles.

⁹Guidotti & al. (2004) provide evidence that economies that trade more, recover more quickly from output contractions that usually accompany “sudden stops”. Calvo & al. (2004) and Edwards (2004) find that openness to trade is associated with fewer “sudden stops”. Martin & Rey (2006), using a general equilibrium model, show that emerging markets are more prone to financial crises unless openness in their financial accounting is counteracted by similar degrees of openness in trade.

¹⁰The rationale for this evidence is that, in the presence of nominal rigidities, currency devaluation gives the country a temporary boost in terms of competitiveness, leaving its trade competitors likely to be the next to be attacked.

1.2 Is Trade Openness “destabilising” for developing countries?

that could hamper international competitiveness; ii) an “income effect”, i.e. reduction in the demand for imports induced by the income reduction following a crisis; iii) a “cheap import effect”, which, by contrast, is a positive supply shock connected to a reduction in import prices by trading partners forced to devalue.¹¹ She highlights also the key role of countries different responses to the initial crisis in determining the prevalence of each effect: e.g., the competitiveness effect is larger in the face of a currency devaluation, while the income effect is mainly linked to a rise in interest rates.

The first impression generated by the above survey is to conclude that applied literature on trade and instability is unstable too. My point here is that the analyses above are not sufficient to have a final say on the issue and that a more rigorous “trade-induced vulnerability to poverty” analysis is needed. The surveyed empirical works use, in fact, numerous different methods and empirical instruments, and studies are separated across widely different fields of investigation which often do not communicate.¹² In addition, most of these investigations are backward looking and mainly targeted at issues not directly linked to vulnerability. Moreover, they are overwhelmingly focused on “output volatility” while there is little investigation on “consumption volatility” and on the relationships between the two.

Before drawing the key directions of research on trade and vulnerability in section 4, it is useful to provide a clear cut conceptualisation of vulnerability and its measurement as well as to highlight the most common misconceptions.

¹¹Analysing data on trade flows for a sample of countries that experienced a crisis in the 1990s, Forbes (2002) suggests that competitiveness and income effects are negative, significant and quantitatively relevant, while the positive cheap import effect remains weak.

¹²Regarding the trade and volatility link, e.g., extensive use of panel data is made to measure the external exposure of a worldwide sample of countries by the sensitivity of first and second moments of economic growth (average rate and standard deviation) to openness and financial shocks (Kose & al., 2003; Hnatkovska & Loayza, 2005; Wolf, 2005; Calderon & al., 2005). Semi-structural VAR (Vector AutoRegressive Models) are applied to panel data in order to isolate and standardize shocks; estimate their impact on GDP and examine whether and to what extent this impact depends on domestic conditions (Loayza & Raddatz, 2007; Santos-Paulino 2010). Malik & Temple (2006), in their effort to explain differences in output volatility across developing countries, used instead a Bayesian method to highlight explanatory variables that are robust across a wide range of specifications. Another interesting exercise to measure variability is proposed in Valenzuela (2006), which attempts to assess whether, in a context of volatile commodity markets, it is possible to discern the effects of trade liberalization on poverty using an innovative application of a stochastic framework in combination with the Global CGE model and a micro-household simulation. An extensive use of Probit models is applied to measure the probability of a sudden stop (Cavallo & Frankel, 2008; Calvo & al., 2003, Frankel & Rose, 1996, Frankel & Wei , 2004, Glick & Rose 1999).

1.3 Vulnerability: Conceptualisation, measurement and common misconceptions

As Hoddinott & Quisumbing (2003) underline, vulnerability means different things to different people. It is a complex phenomenon, not easily determined by one measurable dimension. It can be rightly compared to a picture in a newspaper. Looked at from a distance, it may seem clear and relatively sharp. However, viewed close up, it appears blurred and grainy and loses its sharpness. Likewise, there is a wide consensus on what vulnerability means in general terms; but, when we attempt to analyse it in detail, the concept tends to blur and become subsumed in the haze of the multifarious situations of vulnerability, giving only context-specific interpretations. As a result, a proliferation of methodologies, terminology and approaches to vulnerability analysis have been applied within a broad range of topics (e.g. food security, natural disasters, conflict prevention, economic fragility, etc.). Scholars, research centres, multilateral and bilateral organizations and agencies have developed their own definitions and methods to analyse vulnerability.¹³ It is notable that not all these definitions include the same key elements and they also use slightly different terminology. Hence, practitioners from different disciplines use different meanings and concepts of vulnerability, which tend to be theoretically strong and empirically weak, or vice versa (Alwang & al., 2001).

a. The concept of vulnerability

An attempt to provide a comprehensive definition of vulnerability has been carried out by the World Bank, in its “Social Risk Management” (SRM) approach (Holzmann, 2001; Holzmann & Jorgensen, 2001; Heitzmann & al., 2001).¹⁴ The SRM approach is partly an extension of the literature on poverty dynamics, where the traditional distinction between chronic and transient poverty is enhanced by a forward-looking approach. According to this approach (see Heitzmann & al., 2001), the three basic components of vulnerability analysis are the following:

¹³For an extensive analysis of the methods and tools in international organization, see Montalbano & Triulzi (2002).

¹⁴The aim of the Social Risk Management approach is to embed social protection programs into an integrated approach to poverty reduction. To this extent, the SRM framework is considered as a safety net in times of crisis and hardship, but more importantly a springboard to assist the poor to escape poverty and vulnerability prior to the occurrence of a shock (World Bank, 2000).

1.3 Vulnerability: Conceptualisation, measurement and common misconceptions

- a thorough analysis of risks (i.e. the exogenous side): risks have different nature. Moreover, they can be characterised by a known or unknown probability distribution, by different magnitude (size and spread), history, frequency, correlation, duration, timing and severity. Finally, they may be idiosyncratic (i.e. specific to the household and its members, e.g. illness or job loss), or covariate (i.e. experienced simultaneously, regionally or nationally, e.g. inflation, recession, and terms-of-trade volatility);
- an assessment of the degree of resilience and/or responsiveness (i.e. the endogenous side): Households can respond to or manage risks in several ways, using formal and informal risk managing, mitigating and coping tools. Risk management involves *ex-ante* and *ex-post* actions. Risk mitigation includes formal and informal responses to expected losses such as self-insurance (e.g. precautionary savings), building social networks, and formal insurance based on expansion of the risk pool. Risk coping activities are *ex post* responses and involve activities to deal with actual losses such as selling assets, removing children from school, migration of selected family members, taking temporary employment. The availability of coping mechanisms has to be coupled with the degree of “adaptability” or “resilience” of different households.
- a benchmark: it means a socially accepted minimum norm for each outcome under which households is said to be vulnerable to future loss.¹⁵

Another prominent approach to vulnerability is the “Sustainable Livelihood Vulnerability” (SLV) adopted by many international development agencies, such as UNDP, and with slight differences in terminologies and methods also by DFID, IDS, Oxfam, CARE, to produce project appraisals and reviews (see Carney & al., 1999). The SLV approach is linked to Sen’s seminal “capabilities approach” which stresses what people can do or be, based on their entitlements. Accordingly, SLV assesses vulnerability as the likelihood that people’s livelihoods deteriorate over time, and analyses the dynamics and characteristics of the population’s reaction strategies in various political and socio-economic contexts (Barrientos, 2007; UNDP, 1999 & 2000; Singh & Gilman, 1999). It incorporates an evaluation of sensitivity to negative shocks (“livelihood sensitivity”) as well as the endogenous ability to respond and recover (“livelihood resilience”).¹⁶

¹⁵Standard analyses generally use a poverty line to assess vulnerability to poverty.

¹⁶Efforts have been made to combine the “sustainable livelihood” approach and “en-

1.3 Vulnerability: Conceptualisation, measurement and common misconceptions

b. The measurement of vulnerability

Different approaches to vulnerability lead to different methods of estimation. While SLV adopts a more holistic approach and looks at the capacity of social communities to recover from disasters, monetary analyses of vulnerability typically express welfare in terms of consumption and focus on consumption variability as proxy for economic instability, acknowledging that consumption of an optimizing household changes only in response to unexpected changes in income (Dynan, 1993).

While the earliest efforts attempt to measure vulnerability simply as the negative impact on household's consumption from exposure to a set of observed risks - the so called VER (vulnerability exposure to risk) approach (Glewwe & Hall, 1998; Amin & al., 1999, Dercon & Krishnan, 2000) later efforts measure vulnerability as loss in "expected welfare", variously defined, in an uncertain environment (Chaudhuri, 2001, 2003; Ligon & Schechter, 2003; Calvo & Dercon, 2007a).

A first taxonomy of the main methods applied in vulnerability analysis has been provided by Hoddinott & Quisumbing (2003). A slight update to this identifies three main typologies of vulnerability measures: VEP - Vulnerability as Expected Poverty (Christiaensen & Boisvert, 2000; Christiaensen & Subbarao, 2005; Chaudhuri, 2001, 2003; Chaudhuri & al., 2002; Pritchett & al., 2000; Gunther & Harttgen, 2009); VEU - Vulnerability as Low Expected Utility (Ligon & Schechter 2003, 2004); VTP - Vulnerability as Threat of Future Poverty (Calvo & Dercon, 2003, 2005, 2007a,b). Each of these vulnerability method presents its own virtues and weaknesses (details about these methods and their pros and cons are reported in the Appendix). VEP method is the most commonly applied. The reason is twofold: it is more easily interpretable than utility-based measures since it provides results in terms of expected values of the common FGT class of decomposable poverty measure (Foster & al., 1984); it permits one to assess vulnerability using a single round of cross-sectional data, which is a strong assumption

vironmental vulnerability", where vulnerability is the exposure of individuals or social groups to a reduction in livelihood linked to environmental change (Dinar & al., 1998, Ahmed & Lipton, 1999). Following this approach, methodologies to provide insights into the expected negative impacts of climate change have been developed. However, we should remember the distinction between "socio-economic vulnerability" and "ecological fragility or environmental vulnerability" (Guillamont, 2009). While socio-economic vulnerability can be induced also by natural factors (see, e.g., the undeniably negative impact of earthquakes, typhoons and floods on the sustainability of economic growth), we need to acknowledge that an entire set of issues, such as biodiversity, pollution and global warming, remain exclusively outside this subject and form a separate and specific area of analysis, i.e. "ecological fragility".

1.3 Vulnerability: Conceptualisation, measurement and common misconceptions

but particularly convenient in the absence of panel data, as it is the case for most developing countries. However, it holds, among others, on two additional strong assumptions: i) the variance of log consumption of otherwise equal households is not the same for all households and captures the impact of covariate and idiosyncratic shocks¹⁷ ii) this variance can be explained with observable household and community characteristics. One of the main weakness of the VEP method lies in its somewhat perverse policy implication that is the fact that increasing variance one would reduce the vulnerability of those with mean consumption below the poverty line. VEU is more rigorous in terms of theoretical background but less suitable to be easily transformed into policy prescriptions. It measures vulnerability as the difference between the expected utility of consumption and a minimum acceptable level of utility derived from a certainty-equivalent level of consumption. It helps to disentangle “vulnerability to poverty” from “vulnerability to risk” (i.e., high volatility in consumption). However, it remains sensitive to the choice of the form of the utility function and changes in welfare above the poverty line. Lastly, VTP actually benefits of a rich “axiomatic approach” but pays for it through a limited empirical applicability and the need of lengthy households panels. VTP sees vulnerability as a combination of poverty (measured as failure to reach a minimum outcome) and risk (measured as dispersion over different states of the world), emphasising the sensitivity to risk of the vulnerability measure. It also avoids vulnerability to depend from outcome changes above the poverty line (the so called focus axiom).

Ligon & Schechter (2004), using a set of Monte Carlo experiments to explore the performance of different estimators and vulnerability measures, find that each of the three approaches perform best in different environments. More specifically, when the environment is stationary and consumption expenditures are measured without error, VEP is the best estimator. If the vulnerability measure is risk-sensitive¹⁸ and consumption is measured with error, then VEU and VTP estimators generally perform best. Finally, if the distribution of consumption is non-stationary, a modification of the Chaudhuri (2001) estimator applied to panel data in differences proposed by Pritchett & al. (2000) performs best.

¹⁷As Kamanou & Morduch (2002) and Hoddinott & Quisumbing (2003) point out, a strong homogeneity assumption must be made in order to interpret results of vulnerability, namely that all households observed in the cross-section receive draws from the same distribution of consumption changes. In practice, while one can refine this measure by disaggregating by region, by income group, etc., the assumption of homogeneity still has to be made.

¹⁸According to Ligon & Schechter (2004) a vulnerability measure is “risk sensitive” if it increases when risk increases.

1.3 Vulnerability: Conceptualisation, measurement and common misconceptions

In conclusion, we still lack a single, generally agreed, method to measure vulnerability as well as a common approach to look at uncertainty as a source of distress. Moreover, the above methods focus all on households, no matter what the typology (from handmade macroeconomic policy to natural disasters, e.g. rainfall, etc.) and nature (covariate and idiosyncratic) of the observable shocks. Furthermore, they all make reference to a poverty line (in terms of consumption, income or utils) as a benchmark, narrowing, generally speaking, the assessment of vulnerability into vulnerability to poverty.

c. The most common misconceptions about vulnerability

Notwithstanding the amount of analytical and empirical work on vulnerability, its analysis is still affected by several misconceptions.

1) Vulnerability vs poverty

First, most analyses liken vulnerability to poverty. Although closely related - they can be seen as two sides of the same coin - these two concepts are different. The first obvious remark is that observed poverty status of a household is the *ex-post* realisation of a state, whereas vulnerability is its *ex-ante* probability (Chaudhuri & al., 2002). However, it is worth underlying they both focus on poverty dynamics with a different lens. While, in fact, standard poverty assessments deal with the evidence of the temporary nature of poverty (Baulch & Hoddinott, 2000)¹⁹ trying to separate transient and chronic poverty and providing information on “how often” a household is poor; vulnerability analyses that deal with it distinguish between those who have low expected mean consumption (i.e. low endowment) and those who have high volatility of consumption (i.e. high uninsured income fluctuations), provides additional information on the sources of poverty. Thus, vulnerability analysis, by disentangling those who are considered as vulnerable because of an estimated expected mean consumption below a minimum accepted benchmark from those who have an estimated expected mean above the benchmark but a high estimated variance in consumption provides an answer also to the key question of “why the poor are poor” (Chaudhuri & Datt, 2001, Gunther & Harttgen, 2009). It follows that the characteristics of the vulnerable differ significantly from those of the poor. Hence, targeting only the latter will exclude a significant group of households that are at risk of a

¹⁹Comparing 13 panel studies of developing countries in Latin America, Africa, Asia and Russia, Baulch & Hoddinot (2000) show there is a surprisingly large percentage of temporarily poor households (from a low of 20% to a high of 66%) in relation to the percentage of chronically poor (10% on average, but never more than 25%) for each region.

1.3 Vulnerability: Conceptualisation, measurement and common misconceptions

decline in living standards as well. In other words, the distinction between poverty and vulnerability remains key for economic policy.

A separate but related issue concerns the degree of vulnerability of the poor. The widespread idea is that the poor will be among the most vulnerable people (World Bank, 2000; Calvo & Dercon, 2007a). Empirical analyses show however that shocks occur everywhere along the income distribution and affect poor and non-poor alike (Tesliuc and Lindert, 2004).²⁰ Moreover, the poor can show a higher degree of resilience even if they rely on coping strategies that could damage their growth prospects (Jalan & Ravallion, 1999, Zimmerman & Carter, 2003; Carter & Barrett, 2006; Carter & al., 2007). It follows thus another key difference between resilience and responsiveness it is worth bearing in mind.

II) Resilience vs responsiveness

Another common misconception in vulnerability analysis concerns precisely the distinction between “resilience” or “adaptability” and “responsiveness” or “coping capacity”. Notwithstanding their obvious interconnection, they are different concepts and cannot be considered as a single one. The term “resilience” refers to “the capacity of a system, community or society potentially exposed to hazards to adapt, by resisting or changing in order to reach and maintain an acceptable level of functioning and structure” (UN/ISDR, 2004). “Responsiveness”, on the other hand, measures the availability of policy tools and institutions to cope with, mitigate or avoid the negative effects of external shocks. In the first case, we are dealing with a structural phenomenon given by the complex of individual actions undertaken collectively mainly by private agents, to cope with, mitigate or avoid the negative effects of external shocks. These actions will depend strongly on assets, and levels of education and health and open the way to new conceptual developments - for instance, in the recent debate on adaptation to climate change. In the second case, we are dealing with policies and institutions capable of strengthening or reducing a country’s ability to cope and/or recover from negative shocks. This distinction has been enhanced at the macro level, by separating the issue of “structural vulnerability” which results from endogenous factors that are independent of a country’s current political will, from the issue of “policy vulnerability” which is linked to a country’s political choices or, even more clearly, from the issue of “state fragility” which relates to countries characterized by very low policy-capability scores (Naude & al., 2009a,b; Guillamont, 2009, 2010). A similar distinction is been in the

²⁰The largest relative differences in the incidence of shocks seem to occur across location characteristics, such as the region or area of residence.

1.3 Vulnerability: Conceptualisation, measurement and common misconceptions

“sustainable livelihood” approach, between “coping strategies”, defined as short-term responses to specific shocks, and “adaptive strategies”, or those that entail longer-term changes in behaviour as a result of shocks or stress. Note that, a greater capacity to cope usually builds resilience, and vice-versa.

III) Vulnerability vs *ex post* welfare loss

Furthermore, it should be acknowledged that experiencing an *ex-post* welfare loss is neither necessary nor sufficient for the classification of vulnerable. Vulnerability is an *ex-ante* condition that only potentially may lead to negative outcomes. Therefore, vulnerability cannot be directly observed, but only predicted (Chaudhuri & al., 2001). Vulnerability measures cannot rely only on observable data (e.g, vulnerability does not depend on, say, what consumption expenditures are actually realized, but rather on what they might be, Ligon & Schechter, 2004). The estimation problem in vulnerability analysis generally involves two steps: first, making consumption predictions; second, summarizing their welfare consequences (Ligon & Schechter, 2004). The first step normally implies the use of past realizations of consumption expenditures to estimate the probability of possible future consumption outcomes. This may be relatively easy if the environment is assumed to be stationary (probabilities remain the same across time). However, environments are not stationary in reality, and the probabilities associated with different consumption realizations vary over time (Ligon & Schechter, 2004).

As a matter of fact, vulnerability needs both a factual analysis (i.e. a forward looking measure from the observed facts) and a counterfactual (i.e. another measure for a different world). For instance, the counterfactual for vulnerability measures based on consumption expenditure is the unobservable level of consumption that would have prevailed in the absence of shocks and/or uncertainty (Alwang & al., 2001). This is the most problematic issue in vulnerability analysis. As many empirical studies show, to figure out a counterfactual is intrinsically challenging because individuals cannot easily or accurately quantify the extent/cost of welfare losses from shocks (Tesliuc & Lindert, 2004). Hence, one should rely on indirect estimation methods. A number of methods have been applied so far, from simple augmented specifications of a typical consumption regression with shock dummies (Datt & Hoogeveen, 2000), to an extensive application of the Oaxaca decomposition (Oaxaca, 1973)²¹ or the use of non-parametric density estimations (Di Nardo

²¹The Oaxaca (1973) decomposition provides separate consumption estimations for a sample of households with and without shocks, and a way of partitioning the gap into a part attributable to differences in measured characteristics and a part attributable to the “treatment”. This approach helps to explain the average differences between the two

1.4 Trade-induced vulnerability to poverty: directions for future research

& al., 1996).²²

Finally, as illustrated previously, without any benchmark, the term vulnerability is too imprecise to be practically useful. A mere situation of risk exposure or a simple subjective feeling of vulnerability are not sufficient for policy targeting. Hence, vulnerability should be defined in terms of the potential to fall below a socially accepted minimums and its measurement should include a cut-off or benchmark (Alwang & al., 2001). At the household level, monetary vulnerability measures assess vulnerability *strictu sensu*, as the risk of falling below a poverty line. Similarly, the sustainable livelihood literature defines vulnerability with respect to a minimum livelihood level. With a macro level view Naude et al. (2009) adopt a broader definition of vulnerability as the risk that a “system” will be adversely affected by a shock (encompassing a broad range of welfare measures, benchmarks and shocks).

1.4 Trade-induced vulnerability to poverty: directions for future research

Keeping in mind concepts, misconceptions and methods of vulnerability analyses is of great help to foster current debate on the destabilizing effects of trade openness. This permit, in particular, to draw the main elements of a thorough analysis of “trade-induced vulnerability to poverty” as well as to derive a sound research agenda on the topic.

A number of considerations support the hypothesis of a trade and vulnerability link: Dercon (2001) underlines the role of openness as a vehicle for an entirely new set of shocks and incentives able to put traditional mechanisms under pressure and hamper people’s standard management strategies; Winters (2002) and Winters & al. (2004) suggest that trade openness could alter households’ optimal portfolios, so that their current portfolios become sub-optimal, especially for the poor, because of their poor ability to bear new risks, and weak capabilities to insure themselves against adverse impacts; Ligon (2006) and Calvo & Dercon (2007a) infer that households’ welfare can be negatively affected by uncertainty over future change induced by, among

groups, but is not very helpful for understanding the distributional consequences of shocks.

²²Di Nardo & al. (1996) provide an extension of the Oaxaca decomposition by estimating the distribution of consumption that would have prevailed if all households were spared the negative impact of shocks, giving more weight to those households who are more likely to be under-represented. This distribution is compared with the actual distribution of consumption, and for each bin of the distribution the impact of the shock is determined as the difference between the current and the counterfactual density. For more details, see Tesliuc & Lindert (2004).

1.4 Trade-induced vulnerability to poverty: directions for future research

other things, reductions in barriers to trade.

A comprehensive investigation of this link requires not only the analysis, theoretically and empirically, of the main transmission channels by which trade openness could eventually turn into negative impacts in terms of welfare, but also an assessment of the degree of both resilience and responsiveness of partner countries. It requires as well the agreement of a socially accepted minimum standard or benchmark over which vulnerability is not an issue. The issue of the benchmark is key in a “trade-induced vulnerability” analysis. Approaches that condemn any shock that causes even one individual to suffer a reduction in income are not useful because, given the heterogeneity of households and the strongly redistributive nature of trade shocks, they will condemn virtually any policy intervention (Winters, 2002). Conversely, narrowing “trade-induced vulnerability” to essentially “vulnerability to poverty because of trade openness”, as follows directly from current vulnerability analyses, not only embodies all the limits of standard poverty analyses, but does not take into account a broad range of welfare measures, benchmarks and shocks which turn indeed to be relevant in an open scenario.

To achieve a better understanding of the trade and vulnerability link and a sound method to measure it, I will suggest some refinements to the current literature on the “destabilizing effects” of trade openness and three promising directions for future research which are related to three levels of investigation: macro, micro and meso.

Concerning the refinement of current literature, it is possible to sum up three main weaknesses of applied literature on the “destabilising effects” of trade openness. First, the need to move from *ex post* assessments, based on aggregate volatility or crisis transmission, to *ex-ante* measures of the likelihood and magnitude of experiencing a reduction in well-being induced by trade openness. Second, the need to choose a suitable benchmark to distinguish actual vulnerability from normal variability. Third, the need of a counterfactual, since vulnerability is an *ex-ante* condition and it is not observable. At the micro level, since the data derived from household surveys are severely limited, there is also the need of a better accounting for the actual impacts of external shocks and specific evidence on “man-made” shocks, such as those that derive from the management of economic policies in a globalised world (Dercon, 2001).

Regarding the directions of future research, from a macro point of view the key challenge is to incorporate a forward looking lens to the standard macro literature on cross-country effects of trade openness; from a micro point of view the aim is to assess the welfare impact of covariate and idiosyncratic shocks induced by trade openness at household level; at the meso level, the objective is to derive useful insights and a more comprehensive

1.4 Trade-induced vulnerability to poverty: directions for future research

picture of the vulnerability to trade phenomena by investigating the channels of transmission of external shocks at the subnational level. The first aspect of vulnerability highlights the pervasive and differentiated impact of covariate shocks that are of main interest for international economic policy. The second might help national policymakers to set priorities and calibrate domestic coping mechanisms and safety nets. The third sheds lights on the pervasive role of geography, regional, industry and competition policies.

a) Aggregate vulnerability from international trade

Substantive cross-country evidence claims that trade openness foster income growth and poverty alleviation among trading partners. As Bhagwati and Srinivasan (2002) clearly state “trade does seem to create, even sustain, higher growth”, while Dollar and Kraay (2002; 2004) argue trade openness benefits the poor, given the positive association between overall growth and poor income growth. These results are consistent with trade theory: trade liberalisation, by eliminating price distortions, improves resource allocation, the import of modern technology and, hence, productivity improvements.

The need for a macro approach to vulnerability is grounded in the recognition that, in the current wave of global trade integration, external covariate macro shocks - the result of a perverse combination of international turmoil and economic policy mismanagement - are becoming increasingly and quantitatively important (World Bank, 2000; Eichengreen & Bordo, 2002).²³ As a result, efforts to measure vulnerability on the level of countries are increasing too (Gallopín, 2006; Montalbano & al., 2006, 2008; Guillaumont, 2009; Naude & al., 2009a, 2009b).

Following a broad definition of vulnerability as the likelihood that an economic system would undergo an outcome below a certain benchmark because of a “perturbation” (Naude & al., 2009b), and recalling Hnatkovska & Loayza’s (2005) decomposition method to derive “extreme volatility” of consumption (i.e., large fluctuations above a specified band) as a proxy for “perturbation”, Federici & Montalbano (2012) provide a first empirical cross-country test for vulnerability from trade openness. They investigate the long term relationship, in a large sample of countries, between the portion of “extreme volatility” of consumption linked to trade openness and the deviation of consumption growth from its expected path (derived, using business cycle filters, as a time and country dependent trend). The novelty of this

²³Although some of these crises received considerable attention in the media (Mexico 1995, Southeast Asia 1997, Brazil and Russia 1998, and Argentina 2001), as World Bank (2000) points out, they represent merely the tip of the iceberg that is a much vaster and more complex phenomenon.

1.4 Trade-induced vulnerability to poverty: directions for future research

empirical exercise lies in its ability to add a forward looking lens to existing literature on the effects of volatility on consumption growth, a feasible notion of benchmark and a counterfactual, all essential elements of a vulnerability framework.

However, simple negative associations between trade openness, macroeconomic volatility and consumption growth are not a sufficient condition to derive robust conclusions on the vulnerability of partner countries. At the same time, we should acknowledge that growth may be higher or lower without uncertainty, but welfare will always be higher without (Reis, 2009). Hence, current empirical literature actually underestimates the cost of fluctuations. Additional efforts towards a more comprehensive aggregate vulnerability analysis are needed. This means, first of all, to reach consensus on a workable definition of "aggregate vulnerability" with the aim to limit the playing field of the analysis and avoid the most common misconceptions. Secondly, to provide a more comprehensive assessment, theoretically and empirically, of the permanent effects on welfare of risk, and its macro links with trade openness and global imbalances (Bordo, 2005; Caballero & Krishnamurthy, 2009; Claessens & al., 2010). The next essay represents a first step in this direction since it provides a comprehensive empirical test of the significance and relevance of consumption behaviour under permanent risk. It is theoretically grounded in a precautionary saving framework and empirically grounded in a wide (147 countries) and long cross-country panel setting for the pre-crisis period (1950-2008);

b) Household vulnerability from trade

A macro approach to vulnerability encompasses the limitations of standard cross-section analyses. Moreover, it focuses on aggregate variables and thus deals only with covariant macro shocks at country level (i.e. shocks affecting the variables on average), without taking account of the differences in observable household characteristics and income distributions. As already underlined, vulnerability assessments may differ across social groups within countries, while the relative income positions of households are likely to have important effects on their ability to access adequate tools and coping mechanisms, as underlined by a number of vulnerability analyses. Hence, aggregate vulnerability needs to be complemented by household investigations.

International trade affects the risks faced by households in two ways: by changing the riskiness of existing activities, for instance, by altering the weight of foreign relative to domestic shocks faced by the economy, and by changing the emphasis among the different activities they engage in, for instance, switching from subsistence food crop to cash crops (McCulloch &

1.4 Trade-induced vulnerability to poverty: directions for future research

al. 2001). However, if the above risks are taken knowingly it is not clear if they are welfare worsening, even if the variance increases (Winters, 2002).

Empirical evidence shows that poorer households may be less able than richer ones to protect themselves against the adverse effects of man-made external shocks or to take advantage of the positive opportunities created by policy reforms (Tesliuc & Lindert, 2004). This may explain the unwillingness of some households to pursue high average returns linked to the different activities opened up by trade reforms (see Morduch, 1994). Thus, they suffer the costs of trade reforms without reaping any compensating benefits in the form of higher average earnings. If this is the case, trade openness has pervasive effect on households' optimal portfolios with likely negative effects in the long run (Winters, 2002; Winters & al., 2004; Calvo & Dercon, 2007a).

This issue, though very relevant, has been largely overlooked by trade empirical literature. It implies the capacity to measure the cost and the probability of changes in households' behaviour induced by risk exposure linked to trade openness that generates uncertainty. This needs a factual and a counterfactual analysis alike. Counterfactual analysis should be able to measure the expected level of consumption expenditure in the absence of uncertainty, net of the mean effects generated by trade. From the point of view of the factual analysis, it means acknowledging that keeping "consumption smoothing" as a primary behavioural objective in the midst of trade reforms actually engenders a set of behavioural changes that can produce diversified effects on households' welfare: from "smoothing income" i.e. sacrifice expected profits for greater self-protection (Morduch, 1994) to the sale of assets (Rosenzweig & Wolpin, 1993) and/or risk-sharing (Townsend, 1994, 1995), to changes in many non-marketed investments, including human capital outcomes and life-cycle patterns of consumption expenditure and time allocation (Becker, 1965).²⁴ As Elbers & Gunning (2003) demonstrate, behavioural changes in response to ex-ante uncertainty/risk, even under consumption smoothing hy-

²⁴Other strands of the literature underline the existence of constrained circumstances that may lead individuals to depart from consumption smoothing as well. The "dynamic asset-based approach to poverty" (Zimmerman & Carter, 2003; Carter & Barrett, 2006; Carter & al., 2007) highlights that poorer agents respond to shocks by smoothing productive assets, hence destabilizing consumption and thus possibly dipping to a poverty trap. Carroll (2001) observes the precautionary savings motive can generate a behaviour that is virtually indistinguishable from that generated by a liquidity constraints, by essentially inducing self-imposed reluctance to borrow. Lee & Sawada (2010) demonstrate that the introduction of a liquidity constraint in presence of precautionary savings might negatively affect the behaviour of the poor, by preventing them to raise the optimal amount of savings. This because the possibility of future binding constraints in a standard life cycle model with uncertainty, makes the households accumulate precautionary wealth in the attempt to insure themselves.

1.4 Trade-induced vulnerability to poverty: directions for future research

pothesis, may have substantial welfare costs. Moreover, the potential impact of risk exposure may be much greater than normally estimated by standard vulnerability measures which treat the mean expected consumption as the riskless counterfactual.

A useful attempt to provide an overall assessment of trade reforms on household welfare, was conducted by Niimi & al. (2007). Adopting Glewwe & al.'s (2002), Justino & Litchfield's (2004) and Winters' (2002) conceptual framework, Niimi & al. (2007) analyse the impact of the *Doi Moi* reform process in Vietnam through three channels: prices, employment and wages, and fiscal policies. They provide robust empirical evidence that trade reforms have actually contributed to reducing poverty in Vietnam.²⁵ However, they lack a forward looking approach. It means to investigate whether the process of opening up the Vietnamese economy has also had an identifiable impact on people's behaviour, and long term effects on their welfare, by increasing *ex-ante* their degree of uncertainty towards the future and/or their exposure to risk.

To this end, both the third and the fourth essays represents a step forward. They complement the existing poverty assessments of Vietnam opening up process by presenting workable ways of exploiting the available households' living standard surveys and present both VEP and (extended) VEU assessments from trade openness.

Vulnerability from trade: a meso approach

A meso approach of vulnerability from trade is required to compound the outcomes of cross-country vulnerability analyses with those at household level in "within country" approaches. The need to enrich vulnerability analysis with a "meso" perspective emanates from the consciousness that neither cross country nor household vulnerability assessments, although characterized by relevant virtues, can guarantee an holistic welfare analysis of the risks induced by trade liberalization. The "meso approach" of vulnerability is a totally new - and promising approach that attracts a growing interest among practitioners. Up to now, it is possible to identify basically two main strands of the literature devoted to the meso approach: the "vulnerability of subnational regions approach", which underlines the role of regional-level shocks as a source of covariate risk to households' income and stresses fragility in various domains, such as economic fragility, fragility of ecosystems and fragility related to governance and local institutions; and the "industry level volatility approach", which starts from the assumptions that the analysis of volatility

²⁵They apply a multinomial logit (MNL) model to analyse the probability of being in a particular state, out of several unordered alternatives.

1.4 Trade-induced vulnerability to poverty: directions for future research

across industries and a closer look at the production sector are key to an deep investigation of the impact of shocks on poverty.

Frontrunners of the first strand of the literature, also called “vulnerability of place” (i.e. the vulnerability of people to fall into or remain in poverty owing to being at a particular place) are Naude et al., (2009b). They built a Local Vulnerability Index (LVI) across 354 magisterial districts in South Africa concluding that remoteness, dominance of primary (agricultural) production in a local economy, and low population densities are the dominant features of the most vulnerable sub-national districts. Also Gunther & Harttgen (2009), starting from the traditional VEP method and using a multilevel analysis (Goldstein, 1999), present a method to differentiate the relative importance of covariate shocks at “community level” (i.e. geographically clustered) with idiosyncratic shocks at household level.

Proponents of the “industry level approach” are Imbs (2004), di Giovanni & Levchenko (2009) and Krishna & Levchenko (2009). Imbs (2004) proposes a possible solution to the macro trade co-movement puzzle (see Kose & Yi, 2001, 2006), highlighting the role of intra-industry trade on business cycle synchronization. Di Giovanni & Levchenko (2009), using a broad, industry-level panel dataset of manufacturing production and trade (59 countries and 28 manufacturing sectors over a period of 30 years), highlight that more open the industries tend to be, *ceteris paribus*, the more volatile since they are more exposed to world supply and demand shocks. Krishna & Levchenko (2009) provide theoretical explanations of Koren & Tenreyro’s (2007a) hypothesis that developing countries are more volatile because their production specialisations are in more volatile sectors. They find that less developed countries with low levels of human capital or with lower institutional ability, tend to specialise in less complex goods (i.e. that require fewer inputs for the production of one unit of the good), which are characterised by higher levels of output volatility. This last is a somewhat surprising feature. According to Leontief technology if all inputs are necessary, more inputs imply more risks. Their argument is that the volatility of a good that uses only a few inputs will be more affected by the shocks to each individual input, while production in a sector that uses numerous inputs will be less affected, on average, by shocks to any particular input (see also Koren & Tenreyro, 2007b). As it is apparent, we are still far from a comprehensive analysis of “meso vulnerability”. However, also in this case, very useful, although still scattered, contributions are in place and provide a valuable starting point.

Notwithstanding a through analysis of “meso vulnerability” is outside the scope of this research work, the empirical evidence presented in both Essays 3 and 4 that trade-related risks are not fully shared across trade-related industries consistently highlights the relevance of this issue and the need of

further investigations in this direction.

1.5 Conclusions

Whether - and eventually to what extent - trade openness imply long term welfare discounting for some countries or households by raising their uncertainty about the future and/or their risk exposure to external shocks is still uncertain. Hence, it warrants more careful investigation.

The literature review presented here highlights the amount and extent of the very informative work currently available on this topic and also the urgent need for more focused work on the implications of trade openness in terms of vulnerability. The added value of the present work is to get a comprehensive conceptualisation of vulnerability, its methods and misconceptions, and to highlight three directions for future research in “trade-induced vulnerability” within three levels of analysis: macro, micro and meso. Improving our capacity to assess the vulnerability hazard of different trade reform options, at different levels of analysis, has evident policy implications. Evaluation of the impact of covariate shocks induced by trade openness is of major interest to international economic policy; assessment of trade-related idiosyncratic shocks will help national policymakers to set priorities and calibrate domestic coping mechanisms and safety nets; the “meso” analysis sheds lights on the economic geography and socio-political determinants of “trade-induced vulnerability” as well as on the role of industrial and competition policies.

Appendix 1A - Short summary of the most common vulnerability measures

This appendix provides a short summary on the main available methods to measure monetary vulnerability as well as of their pros and cons.

VEP-Vulnerability as Expected Poverty (Christiaensen & Boisvert, 2000; Christiaensen & Subbarao, 2005; Chaudhuri, 2001, 2003; Chaudhuri & al., 2002; Pritchett & al., 2000).

This is the most controversial but commonly applied method. It assesses vulnerability simply as the expected value of the standard FGT class of decomposable poverty measures (Foster & al., 1984) as follows:

$$V_{\alpha,ht} = F(z) \int_0^z \left(\max \left\{ 0, \frac{z - c_{h,t+1}}{z} \right\} \right)^\alpha \frac{f(c_{h,t+1})}{F(z)} dc_{h,t+1} \quad (1A-1)$$

where c_h is household's consumption; z is the standard poverty line; $F(\cdot)$ and $f(\cdot)$ indicate, respectively, the cumulative distribution and the density function of consumption at time $t + 1$ ²⁶. Eq.1A-1 measures the probability of households to fall below the poverty line, i.e. $F(z)$, multiplied by a conditional probability-weighted function of the shortfall below this poverty line (Christiaensen & Boisvert, 2000). The parameter α sets the degree of sensitivity of the vulnerability measure to the distance from the poverty line.²⁷ When $\alpha = 0$ VEP measure reduces to the probability that the household will experience poverty, i.e $V = F(z)$ ²⁸. The distribution F is taken as given and reflects both the households' exposure to shocks (idiosyncratic or covariant) and its ability to cope with them.

²⁶Eq. 1A-1 is obtained by multiplying the expected value of the poverty index by $F(z)/F(z)$. For more information on the derivation procedure of Eq.1A-1, see Christiaensen & Boisvert, 2000.

²⁷To provide a measure of vulnerability more consistent with the measure of the severity of poverty, Kamanou & Morduch (2002) express vulnerability as expected changes in poverty rather than expected poverty per se. Specifically, they define vulnerability in a population as the difference between the expected value of a poverty measure in the future and its current value (i.e. only the first moment matters), attaching weights to the deviations between the welfare measure and its benchmark.

²⁸The majority of works (Christiaensen and Boisvert, 2000; Pritchett et al., 2000; Chaudhuri and Datt, 2001; Chaudhuri et al., 2002) rely on this choice indeed, but there are also some VEP applications which look at the depth of the poverty ($\alpha = 1$) and at the spread of its distribution ($\alpha = 2$) (see, for example, Ravallion, 1988).

Empirically, on the assumption that consumption is log-normally distributed, setting the consumption poverty threshold, z and a threshold probability value above which a household is considered vulnerable, it is possible to estimate vulnerability to expected poverty as the probability at time t of a household with characteristics X_h to fall below the poverty line in the near future using the estimated expected mean (\hat{c}_h) and variance ($\hat{\sigma}_h^2$) of its log consumption, as follows:

$$V_{\alpha,ht} = Pr(\ln c_{ht} < \ln z | X_h t) = \Phi\left(\frac{\ln z - \ln \hat{c}_h t}{\sqrt{\hat{\sigma}_h^2 t}}\right) \quad (1A-2)$$

where Φ is the cumulative density of the standard normal distribution.

The main assumption of the VEP approach is that environment is stationary and the variance of the residuals in cross-sectional consumption regressions (i.e. the unexplained part of household consumption) is not simply a measurement error and is not equal across households. It rather captures the impact of both idiosyncratic and covariate shocks on consumption, that can be explained by a set of observable household characteristics. It follows from this assumption the main advantage of the VEP method: it can be used to assess vulnerability with a single round of cross-sectional data.

The drawbacks of the VEP method are essentially the lack of a solid theoretical background and the fact it relies on a set of strong assumptions, namely: cross-sectional variability proxies also inter-temporal variance in consumption (hence, it misses the impact of household-invariant but time-variant shocks); time series are stationary; the distribution of shocks to consumption is independent normal; households have increasing absolute risk aversion, (which contrasts to the empirical evidence on the risk preferences of the poor).²⁹ Furthermore, it displays a somewhat perverse feature relating to the measure of the welfare consequences of risks, since it implies a reduction of vulnerability by increasing the variability of consumption around the poverty line, which is in sharp contrast to the poor being risk averse (Hoddinott & Quisumbing, 2003).³⁰ Finally, the standard version of the approach is not able to differentiate between the impact of idiosyncratic shocks and

²⁹VEP method does not deal with households' risk preferences, but this assumption follows directly from the VEP method as noticed by Ligon & Schechter (2004).

³⁰To make this point Hoddinott & Quisumbing (2003) present the following example: consider two possible scenarios. In the first, a risk averse household is certain that expected consumption in period $t+1$ is just below the poverty line so that the probability of poverty (i.e. vulnerability) is 1. In the second, while mean expected consumption remains unchanged, there is a slight variability of consumption such that there is probability 0.5 that the household will have consumption just above the mean (and above the poverty line) and probability 0.5 that the household will have consumption slightly lower than the mean (and the poverty line). Moving from the first scenario to the second, makes

the impact of covariate shocks. Acknowledging the latter caveat, Sarris & Karfakis (2006) and Gunther & Harttgen (2009) present different methods to disentangle VEP measure assessing separately the impact of covariate shocks at the community level and the idiosyncratic ones at household level. More specifically, Gunther & Harttgen (2009) acknowledge the hierarchical structure of community and household variables by applying a multilevel analysis. Hence, they decompose the unexplained variance in households' consumption into a lower-level (i.e. household) and a higher-level (i.e. community) component. Gunther & Harttgen (2009) provide also a sound method to decompose vulnerability estimates into sources of vulnerability. They disentangle the set of vulnerable households into two sub-groups, namely: households with the estimated expected mean consumption below the poverty line (the poverty induced vulnerable) and households with estimated expected mean consumption above the poverty line but characterized by high estimated variance in consumption (the risk induced vulnerable).

VEU - Vulnerability as Low Expected Utility (Ligon & Schechter 2003, 2004).

The VEU model tries to counteract the weak theoretical background of the VEP class of measures by proposing a measure of vulnerability based on expected utility. The vulnerability of household h is thus measured as the difference between the utility derived from some level of certainty-equivalent consumption, zce (above which the household would not be considered vulnerable; something analogous to a poverty line), and the expected utility of consumption ($EU_h(c_h)$), as follows:

$$V_h = U_h(zce) - EU_h(c_h) \quad (1A-3)$$

where U_h is a weakly concave, strictly increasing function.

The VEU method too enables decomposition of vulnerability into two distinct components: vulnerability to poverty, that is, low expected consumption, and vulnerability to risk, that is, high volatility of consumption, as follows:

$$V_h = [U_h(zce) - U_h(E(c_h))] + [U_h(E(c_h)) - EU_h(c_h)] \quad (1A-4)$$

where the first bracketed term (i.e. the difference in utility at zce compared to the utility of households' expected consumption) is a measure of

the household worse off (being risk averse, it would prefer the certain consumption to the expected consumption). However, the second scenario will reduce vulnerability, from 1 to 0.5. The perverse result is that, using this measure, a policymaker seeking to reduce vulnerability should introduce new sources of risks.

vulnerability to poverty and involves no random variables, while the second term, according to the ordinal measures of risk proposed by Rothschild & Stiglitz (1970), measures vulnerability to risk.³¹ Moreover, with this method, different from VEP, the risk component can be further decomposed into covariate and idiosyncratic components. Let $E(c_h|x_t)$ be the expected value of consumption conditional on a vector of covariant variables x_t , then we can rewrite the VEU measure as follows:

$$V_h = [U_h(z_c e) - U_h(Ec_h)] + [U_h(E(c_h)) - E(c_h|x_t)] + [E(c_h|x_t) - EU_h(c_h)] \quad (1A-5)$$

where the first bracketed component is again vulnerability to poverty, but the second and third components break down vulnerability to risk into two sub-components: vulnerability to covariate risks and vulnerability to idiosyncratic risks. To avoid confusion between the measurement error and idiosyncratic risk, Ligon & Schechter (2003) further decompose their measure of idiosyncratic risk into risk that can be attributed to a set of distinct, observed, time varying characteristics.

The VEU measure of vulnerability raises three main and interrelated concerns too: firstly, the obvious circumstance that the choice of the particular functional form of the utility function directly affects the magnitude of the phenomenon³²; secondly, the difficulty to transform VEU measures of vulnerability, in units of utility, into actual economic policy targets (Hoddinott & Quisumbing, 2003); thirdly, it is sensitive overall to *ex-ante* changes in welfare, even those above the poverty line that have no direct incidence on future poverty (Calvo & Dercon, 2007a).

VTP - Vulnerability as the Threat of Poverty (Calvo and Dercon, 2013; Povel, 2015, Chaudhuri et al., 2002; Kamanou & Morduch, 2004; Pritchett, Suryahadi, & Sumarto, 2000; Dutta et al., 2011; Gunther & Maier, 2008).

The VTP class of vulnerability measures tries to avoid some of weaknesses of both VEP and VEU methods. The main advantage of this group of measures is that vulnerability is associated to the extent that poverty cannot be safely ruled out as any of the possible future scenarios (Calvo, 2008).

³¹It is the "natural" counterpart, denominated in utils, of the "risk premium" the household would be willing to forego in order to eliminate the risk. It can be measured, starting from a (weakly) concave utility function, as the difference between the utility of consuming the expected consumption with certainty and the expected utility from consuming c_h .

³²Ligon and Schechter (2003) rely on the Constant Relative Risk Aversion (CRRA) form of the utility function.

Starting from the assumption that people suffer and are wary of the future if their knowledge of what it holds is uncertain, Calvo & Dercon (2007a) assess vulnerability as the *ex-ante* probability weighted average[s] of state-specific indices of deprivation and propose a set of axioms³³ to picture the desirable properties of a vulnerability measure able to endogenously combine poverty and risk measures.

If all the axioms are satisfied, the following vulnerability measure applies:

$$V_\alpha = 1 - E[x^\alpha] \quad (1A-6)$$

with $0 \leq \alpha \leq 1.0 \leq 1$ represents the rate of coverage of basic needs, which is derived, for each state of the world, as $x_i \equiv \tilde{y}_i/z$ where $\tilde{y}_i(y_i, z)$; y_i is the consumption level (after all consumption smoothing efforts have been deployed); z is the standard poverty line; and α represents risk sensitivity (as α increases to 1, household approaches risk-neutrality). It follows then, that people are vulnerable to the extent that poverty cannot be safely ruled out as a possible future scenario (Calvo, 2008). This means that general uncertainty not related to poverty in any state of the world does not enter in this measure of vulnerability. In this respect, the VTP measure overcomes VEP, which, according to this view, risks to overestimate vulnerability and VEU, since the vulnerability measure cannot be affected by outcome changes above the poverty line (i.e., the focus axiom).

Two main caveats apply to use of the VTP measure. Firstly, it follows from the definition above that for those facing no uncertainty with known $x_i = x^* < 1$, for all i , $V_\alpha > 0$; that is, they must be considered vulnerable with certainty. In other words, being poor is the dominant threat in terms of vulnerability. However, there is no agreement on this reasoning in the literature. Moreover, there is also a risk of a spurious correlation between poverty and vulnerability since those households that suffer an income or wealth loss are likely to be at the lower end of the income distribution (Tesliuc & Lindert, 2004). Secondly, the empirical strategy of VTP implies the use of lengthy

³³The set of axioms is the following: the focus axiom (i.e. the vulnerability measure cannot be affected by outcome changes above the poverty line); symmetry over states (i.e. the only relevant difference between two states of the world i and j is the difference in their outcomes and probabilities); continuity and differentiability (of the vulnerability function); scale invariance (i.e. vulnerability measure should not depend on the unit of the measure of outcomes); normalization (i.e. to impose boundaries for reasons of comparability); probability-dependent effect of outcomes (i.e. vulnerability is sensitive to the likelihood of that particular state of the world); probability transfer (i.e. if y_i is greater than or at least equal to y_j , then vulnerability cannot increase as a result of a probability transfer from state j to state i); risk sensitivity (i.e. greater risk increases vulnerability); constant relative risk sensitivity (i.e. risk sensitivity remains constant if all state specific outcomes increase proportionally). Calvo and Dercon (2007).

panel data to retrieve predictions of the rate of coverage of basic needs and the distribution of random idiosyncratic shocks looming for households in the future in various states of the world (Calvo, 2008). This strategy is not exempt from critique. It is not only subject to mis-specifications and measurement errors, but assumes a time invariant discrete uniform distribution of shocks, which is indeed an assumption as strong as proxing inter-temporal variance with cross-sectional variability, as made by the VEP method. As a result, this generous effort of building an axiomatic approach to vulnerability lacks robust empirical analyses capable of providing a clear added value to standard VEP outcomes. It should be borne in mind, generally speaking, the existence of a trade off between more accurate vulnerability estimates and the vast amounts of data required on all possible states of the world.

Chapter 2

Essay 2 - Aggregate risk and consumption behaviour: the empirical evidence in the long run

This essay sheds light on the impact of aggregate (permanent) risk on consumption behaviour. Unlike previous works, the present analysis: i) is theoretically grounded in a precautionary saving framework; ii) is empirically grounded in a wide (147 countries) and long cross-country panel setting for the pre-crisis period (1950-2008); iii) controls for country heterogeneity and also includes the poorest countries in the world. By presenting conservative (i.e., lower bound) estimates, our main conclusion is to highlight a significant association, on average and *ceteris paribus*, between aggregate permanent risk, “extra saving” and consumption. Although consumption fluctuations are seen as the optimal response to risk, this implies a lower smooth path of consumption than the risk-free counterfactual, with permanent negative effects on welfare. This relationship holds in the long run, increases over time and is widespread across the entire income distribution. However, our results empirically confirm Lucas’s (1987) intuition regarding the low value of stabilisation policies.

Keywords: consumption, volatility, risk, precautionary saving, welfare, developing countries.

2.1 Background, aims and caveats

This work contributes to the empirical debate on the impact of macroeconomic fluctuations on welfare by empirically assessing the impact of aggregate (permanent) risk on consumption behaviour. The global crisis of 2008-09 has raised additional concerns about the welfare effect of macroeconomic shocks on public and private saving (Mody et al., 2012; Aizenman and Noy, 2013), especially in developing contexts (Prasad, 2013). While the empirical debate from Ramey and Ramey (1995) onwards has largely focused on the causal impact of macro volatility on long run growth (highlighting a negative relationship for developing countries), we believe that the empirical assessment of the impact of macro-economic fluctuations on welfare needs additional, more careful investigation (Loayza et al., 2007; Reis, 2009).

Since panel data are ideal for testing the theory of consumption but scarce at the micro level, we present conservative (i.e., lower bound) estimates of the relevance and significance of household “extra-saving” under the precautionary saving hypothesis (Carroll, 2001a; Kimball, 1990; Caballero, 1990, Deaton, 1992) based on a long and wide cross-country panel setting (147 countries) for the pre-crisis period (1950-2008). To go beyond averages and control for country heterogeneity, we provide estimates by income deciles as well.

Our main conclusion is that, on average and *ceteris paribus*, a lower consumption smoothing path is significantly associated with permanent risk, producing aggregate “extra saving” and hampering consumption prospects. This relationship holds in the long run and is widespread across the income distribution. However, albeit by reference to conservative estimates, we cannot refute Lucas’s (1987) intuition regarding the low value of stabilisation policies.

As in other similar studies, the aim is not, at this stage, to distinguish between the various sources of macroeconomic fluctuations (productivity or monetary shocks; pure business cycles; long run uncertainty; policy mismanagement, etc.)¹, nor to address the issue of the portfolio choices beneath consumption behaviour,² but rather to highlight empirically the presence of a

¹Parker and Preston (2005) underline four proximate causes of fluctuations in aggregate consumption growth: new information, real interest rate, consumption preference, and risk.

²In this respect, our results should be assumed to be conditional to asset prices. While direct estimates of precautionary wealth may be advisable to let data speak in a much less filtered way (Carroll, 2001b; Carroll and Samwick, 1997), data on wealth cannot be estimated reliably and in a comparable way across countries. Furthermore, it is not yet clear how to translate estimates on wealth into a set of behavioural parameters (Carroll and Kimball, 2008)

2.1 Background, aims and caveats

robust relationship between aggregate permanent risk, consumption smoothing and “extra-saving” by looking at its magnitude; short-run versus long run dynamics and robustness to countries’ heterogeneity. It is also worth noting that our focus is not, at this stage, to determine clear-cut attribution but to present lower bound estimates on the likely change in consumption behaviour in countries characterised by significant aggregate fluctuation as well as to assess possible traces of “extra-saving” in poor countries. Since income and consumption fluctuations are growing over time (and cannot be considered only as a negative spill-over of the global crisis) this is a relevant issue for policymaking.

The empirical strategy is grounded on the theory of precautionary saving and looks at the impacts of permanent risk on consumption behaviour. According to the precautionary saving literature, consumption adjustments (e.g., reducing current consumption and encouraging additional/extra saving) are seen as optimal responses to meaningful uncertainty in future income (Carroll, 2001a; Kimball, 1990; Caballero, 1990, Deaton, 1992). The literature on precautionary saving is mainly focused on individuals in a closed economy setting. Surprisingly little attention has been devoted to its aggregate counterpart in a global framework (significant exceptions are Ghosh and Ostry, 1995 and 1997; Krussell and Smith, 1998; Carroll, 2000 and, more recently, Mody et al., 2012; Cherif and Hasanov, 2012; Baiardi et al., 2013). Our contribution is an effort to bridge this gap and give additional insights into the impact of aggregate risk on countries’ welfare.

A number of caveats must be taken when performing this empirical task. The main drawback is represented by the implicit assumption that there is a representative agent (i.e., no individual differences). While convenient - it permits the adoption of an invariant felicity function and reduces the problem of measurement error - it implies that incomes are perfectly pooled across individuals (i.e., full domestic risk sharing) and, hence, limits the analysis to aggregate risk only.³ In this respect, our empirical results can be seen as a conservative estimate of the phenomenon under analysis since the direc-

³The usual concern is that the representative consumer model reduces the relevance of precautionary saving (Carroll, 2000). The representative agent story can be even more misleading in the presence of borrowing restrictions that could alter uniformity across individuals. However, as Krussell and Smith (1998), Heaton and Lucas (1996) and Constantinides and Duffie (1996) argue, household heterogeneity arises mostly from idiosyncratic transitory shocks which are easy to insure with only a modest amount of saving (Gourinchas, 2000). Conversely, in a world full of uncertainty, the precautionary demand for saving is likely to be strengthened if access to credit is limited when it is most required (Deaton, 1992; Lee and Sawada, 2010). Moreover, several recent studies controlling for incomplete risk sharing and heterogeneous agents find only modest effects on welfare estimates with respect to Lucas’s benchmark (Lucas, 2003; Krussell et al., 2012; Krebs, 2003)

2.1 Background, aims and caveats

tion of distortion of our aggregate estimates is likely to reduce the impact of volatility rather than emphasise it (the average variability of the individual is greater than the variability of individuals whose behaviour is being averaged). The same consideration applies for another theoretical prediction: the presence of full international risk sharing (i.e., perfect consumption smoothing across countries and states of nature) in the hypothesis of complete markets (Obstfeld and Rogoff, 1996).⁴

Lastly, consumption smoothing is not the only behavioural mechanism to respond to risk and uncertainty. For instance, prudent households under risk may well decide to reduce their health care and school expenditure, contributing in this way to a permanent reduction in income and welfare. However, consumption behaviour is undeniably one of the most relevant household choices under risk. Since saving-ratios tend to be pro-cyclical (rising in boom times and falling in times of crisis), consumption should be assumed, in a macroeconomic perspective, to be protected against business-cycle fluctuations (Deaton, 1992). Violation of this assumption reveals that people react to risk by modifying their consumption behaviour, specifically by reducing current consumption and encouraging additional/extra saving. This implies a lower smooth path of consumption than a risk-free counterfactual with permanent negative effects on welfare. This could arise for various reasons. Risk exposure could generate behaviour that is virtually indistinguishable from that generated by a liquidity constraint by inducing self-imposed reluctance to borrow (Carroll, 2001a). Alternatively, liquidity constraints could make people accumulate precautionary wealth in an attempt to insure themselves (Lee & Sawada, 2010).⁵ Consumption smoothing also engenders a set of behavioural changes apt to produce likely effects on household welfare such as smoothing asset/income; self-insurance, risk-sharing arrangements, diversification, migration, etc. (Morduch, 1994; Rosenzweig & Wolpin, 1993; Townsend, 1994, 1995; Zimmerman and Carter 2003).

The work is organised as follows: Section 2 briefly summarises the literature; Section 3 presents the empirical model; Section 4 shows the cross-country estimates and Section 5 concludes.

⁴In this framework, the only type of risk reflected by consumption is due to aggregate uncertainty over world output (i.e., systemic risk). However, also in this case, the empirical literature has systematically rejected the null hypothesis of complete risk sharing, acknowledging a much larger degree of risk sharing within countries than cross-countries (Crucini and Hess, 2000; Kose et al., 2003, 2007, 2009 and 2011; Asdrubali and Kim, 2008; Broner and Ventura, 2011, Pierucci and Ventura, 2012).

⁵Madsen and McAleer (2000) provide some support for the uncertainty hypothesis, using panel data for 22 OECD countries.

2.2 Why should we care about macro-volatility? A review of the literature

The phenomenon of macro volatility has been confined to standard cycle theory for a long time and was mainly concerned with the decomposition of economic growth into cyclical and trend components. Thus, it has long been considered a second-order issue in studies on developing countries, but of primary interest in industrial countries concerned with smoothing the fluctuations of their business cycles. Moreover, according to the influential Lucas (1987) study, the cost of fluctuations is supposed to be of little account in terms of welfare. The fraction of consumption forgone for a reduction in its variability is approximated by the reduction in the squared coefficient of variation multiplied by half the coefficient of relative risk-aversion. Hence, the value of so-called “economic stabilisation” policies is supposed to be low. However, Lucas (1988) observed that, in the long term, fluctuations in rates of growth are likely to be more substantial in less developed countries, suggesting a link between a country’s level of economic development and its volatility. Recent empirical evidence questions Lucas’s (1987) results. While Lucas conveniently assumed consumption shocks to be serially uncorrelated, Reis (2009) points out that Lucas’s estimates are downward-biased, since he belittled the role of “persistence” as a crucial determinant of the cost of fluctuation.

This weakness is supposed to be more serious in the context of developing countries (Calderon and Fuentes, 2010). From the work of Ramey and Ramey (1995) onwards empirical cross-country studies have consistently found that volatility exerts a significant negative impact on long-run growth. Moreover, they show that it severely affects developing economies’ welfare (Fatas, 2000; Pallage and Robe, 2003; Wolf, 2005; Aizenman and Pinto, 2005; Loayza et al., 2007) and that consumption volatility increases compared with income volatility (Kose et al., 2003). More recently, Malik and Temple (2009) argue that volatility should be assumed as “endemic” in the developing world. They show that the median standard deviation of annual growth rates in low-income countries has been more than three times that of OECD member countries over a period of 40 years (1960-99). The World Bank, in its volatility handbook, also claimed that, in the developing world, “good times do not offset the negative impact of bad times” and shocks tend to have permanent negative effects (Aizenman and Pinto, 2005). According to a number of scholars, such asymmetry is reinforced by internal factors such as incomplete markets, inefficient taxation, pro-cyclical fiscal policy and especially, weak financial market institutions (Easterly et al., 2001; Denizer et

2.2 Why should we care about macro-volatility? A review of the literature

al., 2002; Ferreira da Silva, 2002; Bekaert et al., 2005). Other factors include political insecurity, macroeconomic instability and institutional weaknesses – all phenomena that largely affect developing countries (Alesina et al., 1999; Judson and Orphanides, 1999; Gavin and Hausmann, 1996; Raddatz 2006; Servén, 1997; Agénor et al., 2000; Fatás and Mihov 2005; Acemoglu et al., 2003; Rodrik, 1998 and 1999). Volatility, in this context, is seen as a proxy of “uncertainty”, likely to lead firms either to under-invest or to invest in the “wrong” projects (Caballero, 1991; Bertola and Caballero 1994; Servén, 1997; Aizenman and Marion, 1999) and households to abandon a smooth path of consumption. This behaviour is enhanced by conditions of risk aversion, incomplete markets, lumpiness and the irreversibility associated with the investment process (Hnatkovska and Loyaza, 2005). More recently, the literature has also investigated the plausibility of an overall negative effect of cyclical fluctuations on long-term growth (Fatas, 2000; Blackburn and Pelloni, 2004 and 2005), overcoming the standard distinction between the two issues.

Loayza & al. (2007) highlight two main reasons why we should care about macroeconomic fluctuation: i) the substantial welfare loss of deviating from a smooth path of consumption; ii) the indirect welfare loss in terms of future consumption, in the case of a negative impact of volatility on growth. They also argue that these phenomena are emphasised in developing countries which not only face more volatility than industrial countries, but suffer larger volatility effects, because of the intrinsic instability of the process of development (mainly linked to the weakness of their financial systems and the main characteristics of their specialisation process of production); the concrete risk of policy mismanagement (e.g., as in the case of pro-cyclical and/or erratic fiscal and monetary policies) and the presence of weaker mitigating and coping mechanisms.

More recently, additional empirical cross-country evidence (Mody et al., 2012 and Cherif and Hasanov, 2012) shows how heightened uncertainty has increased precautionary saving in safe assets, leading countries into a “volatility trap”. Likewise, Carrière-Swallow and Céspedes (2013) highlight the presence of strong heterogeneity in the impact of uncertainty on countries’ welfare with emerging markets suffering a much more severe and persistent fall in investment than the other countries in the sample.

The empirical framework adopted in this essay aims to explore the first direct channel of the impact of macroeconomic fluctuations highlighted by Loayza et al. (2007). In this respect, this work differs from the strand of the literature that looks primarily at the second (indirect) channel (Ramey and Ramey, 1995, Fatas, 2000; Pallage and Robe, 2003; Wolf, 2005; Aizenman and Pinto, 2005; Loayza et al., 2007). It also differs from the one that

2.3 Macro-volatility and consumption smoothing: the empirical model

looks directly at the observed aggregate consumption to calculate the gains from eliminating fluctuations in consumption using compensation parameters of household preference for stability (Lucas, 1987, 2003; Reis, 2009). In other words, this Essay focuses on the impact of ex-ante risk on current and future consumption possibilities which implies relative changes in portfolio allocation between risky capital and safe assets. Taking advantage of the long panel data available for aggregate variables, it exploits Euler restrictions to estimate the ex-ante impact of income risk even in the absence of a fully specified dynamic model.

2.3 Macro-volatility and consumption smoothing: the empirical model

To assess the cost of fluctuations on consumption behaviour the obvious theoretical reference is the theory of "precautionary saving" (Carroll, 2001; Kimball, 1990; Caballero, 1990; Deaton, 1992). According to this strand of the literature, if the marginal utility of consumption function is convex, the consumer follows prudent behaviour.⁶ This means that an individual pays attention not only to the mean of the future income (as implicitly assumed by the standard permanent consumption model) but also to its variability. Although the qualitative and quantitative aspects of the theory of precautionary saving (whose basic intuition dates back to Keynes) are now well established, less agreement exists about the strength of the precautionary motive (Carroll and Kimball, 2008) and little attention has been devoted to its aggregate counterpart. Furthermore, the impact of the precautionary motive in developing contexts remains somewhat ambiguous and calls for additional empirical investigation. Deaton (1992) - the first to provide evidence of the cost of precautionary saving on household welfare in developing contexts - highlights a positive effect of risk/uncertainty on saving and growth. Conversely, Hahn (1970), Dercon (2005), Elbers et al. (2009) and Gunning (2010) show how the introduction of risky assets produces, under a series

⁶Although often confused, precaution and risk aversion are not exactly the same thing (Carroll and Kimball, 2008). While prudence represents the "intensity" of the precautionary saving motive, risk aversion determines the price one is willing to pay to eliminate uncertainty. Practically speaking, the degree of precaution is the degree of convexity of the marginal utility function, whereas risk aversion is controlled by the degree of concavity of the utility function. Hence, while precaution depends on the third derivative of the utility function, risk aversion depends on the second derivative and one can be inferred from the other only for very special functions, e.g. if utility is exponential, then absolute prudence coincides with absolute risk aversion (Kimball, 1990).

2.3 Macro-volatility and consumption smoothing: the empirical model

of specific circumstances, negative effects of risk and uncertainty on saving decisions.

Our cross-country comparison adds a long-term perspective (not available at the micro level) to look at the impact of permanent risks on labour income. Furthermore, it could help in assessing whether and to what extent, on average and *ceteris paribus*, aggregate precautionary saving behaviour in developing countries is statistically different from that in more developed contexts.

The standard approach to testing the impact of income risk on causing representative agents to deviate from consumption smoothing is to assume that agents maximise the expected value of the following time-separable Constant Absolute Risk Aversion (CARA) utility function⁷ over an infinite horizon (see Blanchard and Fischer (1989), Caballero (1990 and 1991), Weil (1990), Guiso et al., (1992) among others)⁸:

$$\max E_t \left[\sum_{t=0}^{\infty} \beta^t e^{-\rho c_t} \right] \quad (1)$$

where β is a subjective discount rate of consumption (time preference) and ρ is the degree of absolute risk aversion. Eq. (1) is subject to a standard budget constraint $w_{t+1} = R w_t + y_{t+1} - c_{t+1}$ where $R = (1 + r)$ is the interest factor (assumed to be constant); w is individual wealth (w_t is given) and y_t is the consumer's idiosyncratic income. For now let's assume that the latter exhibits a random-walk deviation from an exogenously growing measure of permanent income: $y_{t+1} = \hat{y}_t + \psi_{t+1}$.⁹ In the simplified case where $R\beta = 1$ and if income shocks are normally distributed, the solution of the system is the following (see Appendix A):

⁷Notwithstanding the fact that the adoption of the Constant Relative Risk Aversion (CRRA) isoelastic utility function is standard in models of precautionary saving (Carroll et al., 1992; Carroll and Samwick, 1997 & 1998; Deaton 1992; Zeldes 1989, Skinner 1988), with a stochastic income process it does not allow a closed form solution. To assess the cost of fluctuations in income, therefore, the only solution left is to apply a negative exponential utility function with Constant Absolute Risk Aversion (CARA) which allows for a closed form solution for the consumption function. The CARA utility function is the following: $U(C) = -\frac{1}{\rho} e^{-\rho C}$ where ρ is the coefficient of absolute risk aversion ($\rho = -\frac{U''}{U'} > 0$). CARA application also has its drawbacks since it implies that the degree of risk aversion is constant (i.e., independent of the level of individual resources) and it does not rule out negative consumption, especially early in life, if assets are low and income innovations are variable (Deaton, 1992).

⁸The hypothesis of infinite time horizon is standard in macroeconomics and reasonable when the focus is on households and not on individuals.

⁹In appendix 2B, we further decompose this measure of permanent income to assess separately the permanent and transitory stochastic components.

2.3 Macro-volatility and consumption smoothing: the empirical model

$$c_t = w_t \frac{R-1}{R} + \hat{y}_t - (R-1) \frac{\frac{1}{2}\rho}{(1-R)^2} \sigma_\psi^2 \quad (2)$$

Eq. (2) adds to the certainty equivalent consumption a negative term on the right hand side that is precautionary saving. It is evident from the fact that it equals zero if there is no risk $\sigma_\psi^2 = 0$ or no precautionary motive $\rho = 0$.¹⁰ Note that, according to this model, the effect of risk on consumption does not depend on the level of permanent income or the level of wealth.

Eq. (2) assumes that consumption tracks permanent income in the long run (which is reasonable in an aggregate framework thanks to the turnover of generations, Deaton, 1992). However, consumption also shows sensitivity to transitory income in the short-run and consumers take some time to adjust their consumption to long-run equilibrium.¹¹ It means technically that consumption and total income are co-integrated.¹²

To control for this and provide a full account of the separate (short-term and long-term) components of the consumption function as well as the adjustment mechanism that links short-term and long-term consumption-income equilibria, we apply an autoregressive distributed lag (ARDL) (1,1) version of our consumption model, as follows:¹³

$$c_t = \beta_0 + \beta_1 y_t + \beta_2 y_{t-1} + \beta_3 c_{t-1} + u_t \quad (3)$$

¹⁰Because of the use of exponential utility in this exercise, the degree of absolute risk aversion is assumed to be equal to the degree of absolute prudence.

¹¹Probably linked to imperfect information and the correlated small individual mistakes in consumption choices.

¹²Indeed, Fisher-type tests do not exclude "unit-root" problems even when cross-sectional averages and linear time trends are taken explicitly into account. Following up the Im–Pesaran–Shin (IPS) approach, the Fisher test performs a unit-root test on each panel series separately, then combines the p-values to obtain an overall test of whether the panel series contains a unit root. The starting point for the test is a set of Dickey–Fuller regressions of the form: $\Delta Y_{it} = \phi_i Y_{it-1} + Z_{it} \gamma_i + \varepsilon_{it}$ where ϕ_i is panel-specific. The null hypothesis is $H_0 : \phi_i = 0$ for all i versus the alternative $H_a : \phi_i < 0$. $Z_{it} \gamma_i$ represent panel-specific means (fixed effects) and linear time trends that describes the process by which the series is generated. Our test uses Newey–West standard errors (i.e., based on heteroskedasticity- and autocorrelation-consistent covariance matrix estimator) to account for serial correlation.

¹³The generic form of the Autoregressive Distributed Lags-ARDL (p,q) process applied to consumption function is the following:

$$c_t = \alpha_0 + \alpha_1 y_t + \alpha_2 y_{t-1} + \dots + \alpha_p y_{t-p} + \gamma_1 c_{t-1} + \dots + \gamma_q c_{t-q} + u_t$$

Our aim is to reach a version of this ARDL process with white noise errors and the minimum number of lags.

2.3 Macro-volatility and consumption smoothing: the empirical model

From Eq.(3) we can derive the steady state equation:¹⁴

$$c^* = \frac{\beta_0}{(1 - \beta_3)} + \frac{\beta_1 + \beta_2}{(1 - \beta_3)} Y^* \quad (4)$$

where $\beta = \frac{\beta_1 + \beta_2}{(1 - \beta_3)}$ is the long-term marginal propensity to consume.

If we subtract c_{t-1} from both sides Eq.(3) and take into account the steady state (long-term) equilibrium by acknowledging from Eq.4 that $\beta_2 = \beta(1 - \beta_3) - \beta_1$ we get:¹⁵

$$c_t - c_{t-1} = \beta_0 + \beta_1(y_t - y_{t-1}) - (1 - \beta_3)[c_{t-1} - \beta y_{t-1}] + u_t \quad (5)$$

where $[c_{t-1} - \beta y_{t-1}]$ is the error correction mechanism (Hendry, 1995; Hamilton, 1994); β is the long-term parameter; β_1 is the short-term parameter (attached to variables in differences) and $(1 - \beta_3)$ is the speed of the adjustment process from short-term to long-term equilibrium (the EC term).

Eq. (5) can be estimated without constraints as follows:

$$\Delta c_t = \beta_0 + \beta_1 \Delta y_t - (1 - \beta_3)c_{t-1} + \beta(1 - \beta_3)y_{t-1} + u_t \quad (6)$$

where Δ is the first difference operator.

From Eq. (6) we derive the following empirical model:

$$\Delta c_t = \delta_0 + \delta_1 \Delta y_t + \delta_2 c_{t-1} + \delta_3 y_{t-1} + u_t \quad (7)$$

where:

$\delta_0 = \beta_0$ [the constant]

$\delta_1 = \beta_1 = c$ [the short-run propensity of consumption]

$\delta_2 = -(1 - \beta_3)$ [i.e. the EC term]

$\delta_3 = \beta(1 - \beta_3)$ [where β is the long-term propensity of consumption]

By applying an Error Correction Model (ECM), this framework is able to link both the short-term and long-term components of the consumption function in a way that is consistent with the standard stylised facts on consumption (i.e., consumption proportional to permanent income in the long run and to current income in the short run). The consistency of this model with permanent consumption theory is generally acknowledged by the empirical condition that the sum of δ_2 and δ_3 approximate statistically to zero (i.e., $\beta = 1$).

¹⁴Steady state is non-stochastic [$E_t(u_t) = 0$] and variables are supposed to be in equilibrium at a constant level as follows:

$c_t = c_{t-1} = C^*$ and $y_t = y_{t-1} = Y^*$

¹⁵For details, please refer to Appendix 2C

2.4 The empirical strategy and cross-country estimates

While in equilibrium certainty equivalence holds by definition, according to Eq. (2), under the log normality assumption¹⁶, precautionary saving is proportional to the variance of income shocks. Hence, the precautionary saving version of Eq. (7) is the following:

$$\Delta c_{it} = \delta_0 + \delta_1 \Delta y_{it} + \delta_2 c_{it-1} + \delta_3 y_{it-1} + \delta_4 \sigma_{id}^2 + u_{it} \quad (8)$$

where $\delta_4 = -(R-1)\frac{\frac{1}{2}\rho}{(1-R)^2}$. It is worth noting that Δc_{it} has been derived by subtracting c_{t-1} from both sides of Eq.(3) and hence here it does not represent the consumption slope. As standard in this literature in this paper we only refer to labour income (i.e., excluding capital income). This lets us treat income as outside the agents' control and assess the consumption consequences of unanticipated shocks (whereas capital income depends at least partially on assets and portfolio choices of households).

2.4 The empirical strategy and cross-country estimates

2.4.1 The empirical strategy

To estimate Eq.(8) we need to handle the classical dynamic panel bias (Nickell, 1981) i.e., the presence of a positive correlation between the lagged dependent variable and the error.¹⁷ Since our panel is balanced, we first apply the Least Square Dummy Variable (LSDV) estimator.¹⁸ Notwithstanding that the residuals of the ARDL specification are not expected to show any systematic component,¹⁹ we repeat the estimation by using the Arellano-Bover/Blundell-Bond system generalised method of moments (SGMM) estimator (Arellano and Bover 1995; Blundell and Bond 1998).²⁰ The motivation

¹⁶Traditional models assume the log normality of consumption from the log normality of permanent income. Battistin et al. (2009) demonstrate empirically that the distribution of consumption expenditures across households is closer to log normal than the distribution of income.

¹⁷By construction, unobserved panel-level fixed effects are correlated with the lagged dependent variable

¹⁸Note that it could argued that the dynamic panel bias is actually not a major issue for our full sample estimates since $T \geq 30$ (Roodman, 2009).

¹⁹As expected, Fisher type tests now reject the presence of a “unit-root” problem.

²⁰The Arellano-Bover/Blundell-Bond SGMM estimator augments the Arellano and Bond (1991) GMM estimator built on Holtz-Eakin et al. (1988) by including lagged level as well as lagged difference in a system of two equations (the original and the transformed ones). The first difference transformation is applied here since our panel is strongly balanced (Roodman, 2009).

2.4 The empirical strategy and cross-country estimates

for using the SGMM estimator instead of the GMM one is the recognition that lags are likely to be weak instruments in the context of the Arellano and Bond (1991) GMM estimator if consumption is expected to be persistent.²¹

Moreover, since risk/volatility effects are also supposed to be persistent (Reis, 2009) and to control for the likely correlation between permanent risk and errors determined by replacing expected values with observed means, we present additional SGMM estimates where risk is assumed as a predetermined variable.²² Thus, we use lagged values of risk/volatility as instruments only for the period in which they are supposed to be unrelated to the error term (i.e., lags higher than three for the first difference equation).²³ Furthermore, we control for the possible spatial cross-sectional dependence of panel data.²⁴ Moreover, even if observed variables are in real terms and first differencing removes any time invariant components of the model, we

²¹When the time series are persistent and the number of time series observations is small, the first-differenced GMM estimator is poorly behaved. The reason is that, under these conditions, lagged levels of the variables are only weak instruments for subsequent first-differences (Bond et al., 2001). The system estimator exploits an assumption regarding the initial conditions to obtain moment conditions that remain informative even for persistent series, and it has been shown to perform well in simulations. Specifically, the system GMM estimator combines the standard set of equations in first-differences with suitably lagged levels as instruments, with an additional set of equations in levels with suitably lagged first-differences as instruments. Although variables in levels are necessarily correlated with country-specific effects, it assumes that variables in first-differences are not correlated with the country-specific effects used as instruments in the level equations. The validity of these additional instruments can be tested by using the standard tests of over-identifying restrictions. Practically speaking, instead of transforming the regressors to expunge the fixed effects, it transforms the instruments to make them exogenous to fixed effects. This is valid assuming that changes in any instrumenting variable are uncorrelated with observed country fixed effects (i.e., countries are not too far from steady states, in the sense that deviations from long-run means are not systematically related to fixed effects). It is worth noting that assuming the opposite (i.e., first-differences correlated with country-specific effects) would result in implausible long-run implications (Bond et al., 2001).

²²This means we allow the error term at time t to have some feedback on the subsequent realisations of the risk/volatility term at time t . More formally, $E(vol_{is}\varepsilon_{it}) = 0$ for $s \leq t$ and $E(vol_{is}\varepsilon_{it}) \neq 0$ for $s > t$. *vol* is volatility.

²³The STATA command `xtabond2` has been applied to run the SGMM estimates, whereas the more flexible STATA command `xtdpd` has been applied for running the additional SGMM estimates with risk/volatility as predetermined variables.

²⁴The assumption that the disturbances of a panel model are cross-sectionally independent is often inappropriate (so called "pure heteroscedasticity"). Provided that the unobservable common factors are uncorrelated with the explanatory variables, the coefficient estimates from standard panel estimators are still consistent (but inefficient). However, the standard error estimates of commonly applied covariance matrix estimation techniques are biased and hence statistical inference that is based on such standard errors is invalid (see Driscoll and Kraay, 1998; Hoechle, 2007).

2.4 The empirical strategy and cross-country estimates

include time dummies to remove any residual time variant component that can impact consumption behaviour other than volatility and observables. This makes the assumption that there is no correlation across countries in the idiosyncratic disturbances more likely.

With regard to our proxy for risk, in line with the classical literature in the field (Guiso et al., 1992; Hubbard et al., 1994; Carroll and Samwick, 1997; Gourinchas and Parker, 2002; Meghir and Pistaferri, 2004; Storesletten et al., 2004; Krebs et al., 2010; Reis, 2009) we filtered out the permanent component of income innovation for each country i in the sample (for more details, see Appendix B). The assumption is that the ability to smooth consumption changes according to the degree of shock persistence, with likely deviations from the consumption smoothing of permanent risk (which is assumed to be fully persistent) being larger than that for transitory ones. This reinforces our aim to make conservative estimates since the relevance and significance of transitory income shocks in causing deviations from consumption smoothing are not addressed here.

Fig. 1 provides a glance into the long-run relationship between volatility of per capita consumption growth and per capita GDP across our sample of 147 countries in the period 1950-2008 (the full list of countries included in the sample, divided into deciles for different decades, is provided in Tables 2D-1 and 2D-2 in Appendix 2D).

The figure highlights the well-known evidence of strong heterogeneity in consumption volatility according to the income levels of the countries in the sample. Specifically, richer countries show a lower degree of consumption volatility, than poorer ones. This leads us to investigate whether differences in countries' income levels actually produce diversified effects both in their short-term and long-term consumption dynamics as well as in their precautionary saving behaviour. A workable way to look at this source of countries' heterogeneity is to provide consumption estimates by income deciles.²⁵

2.4.2 Data

We provide estimates for a panel of 147 countries in a long-term pre-crisis period (1950-2008). Data come from the PWT 7.0 database which is the most widely used source for cross-country comparisons (Johnson et al., 2013). They have been extensively used in various fields of economics including growth, development and international trade. Data in the PWT are measured at purchasing power parity and have covered a large number of

²⁵This means we rely on mean group estimators of the parameters, i.e., not imposing that both short-term and long-term parameters are the same across groups. See Pesaran and Smith, 1995.

2.4 The empirical strategy and cross-country estimates

Figure 1: Volatility and per capita GDP in the long run

countries from all regions for more than 50 years. The ultimate objective of the PWT is to adjust national estimates of GDP by valuing output at common international (purchasing power parity [PPP]) prices so that the resulting PPP-adjusted estimates of GDP are comparable across countries. This allows researchers to make real quantity comparisons both across countries and over time. As a matter of fact, roughly two-thirds of all cross-country empirical work is based on the PWT. Second place is held by the World Bank’s World Development Indicators (WDI) which were originally based on the PWT, but have subsequently diverged. The IMF’s World Economic Outlook (WEO) dataset comes a distant third (Johnson et al., 2013). Recently, the PWT methodology came under some criticism. Ponomareva & Katayama (2010) were among the first to argue that outcomes from the PWT could be version-dependent. They noted that in case of “classical” measurement errors, where the growth rate is the LHS variable, measurement error results only in inefficiency (it is captured by the random error term of the regression). However, Johnson et al. (2013) highlighted that this variability across alternative versions of the PWT stems, in fact, only in part from random changes to underlying national income accounts data.

2.4 The empirical strategy and cross-country estimates

It also seems to be systematically related (inversely) to the size of a country and to the distance of the data from the benchmark data. Hence, when the PPP-adjusted GDP appears as an independent variable (in level or growth) in the regression estimation, measurement errors actually produce biased results. Although challenging, Johnson et al. (2013) demonstrate that this further source of bias could be corrected econometrically. Carrying out careful robustness checks, they argue that the use of a good instrumentation strategy helps to overcome these additional sources of measurement errors in the PWT. Moreover, they demonstrate that while studies that use annual data are less robust, low frequency data remain more robust. All things considered, the use of SGMM technique appears to be the best strategy to adopt also for this purpose, provided that proof of instrument validity is supplied using the appropriate tests (see the following sub-section). Also, assuming that low frequency data are more robust, as a further robustness check for the validity of the estimates, the consistency of annual empirical outcomes with those obtained by averaging data on 3-year spans will be tested as well.²⁶

Specifically, we make use of the following variables: the per capita consumption share of real gross domestic product to derive our proxy of real per capita consumption and the PPP Converted GDP Laspeyres per worker at 2005 constant prices to derive our proxy of real labour income (Table 2D-3 in Appendix 2D provides some descriptive statistics). All variables are in 2005 international dollars per person. According to the PWT, workers' definition includes all status categories of persons in employment, not only employees, including paid family workers, employers, own-account workers, members of producers' cooperatives, contributing family workers and workers not classifiable by status. The choice to use GDP per worker is driven by the fact that national labour income is likely to be misreported especially where there are high rates of informality, unemployment and short-term work, and that the income of self-employed workers is not directly observable. Moreover, in most developing countries, the assumption that the self-employed earn the same average wage as employees would be misleading since the share of employees in the total number of persons engaged (employees + self-employed) is below 50 percent (Inklaar & Timmer, 2013). On top of that, there is a clear lack of consistency across methods used by national accounts and labour surveys in different countries. Of course, this choice rests on the assumption that real wages should track labour productivity in the long run. The use of the SGMM technique helps to control for potential sources of unobserved

²⁶Note that lower frequency exercises would not be compatible with our empirical analysis. They would smooth excessively the data and would cause a dramatic reduction in the number of observations.

2.4 The empirical strategy and cross-country estimates

heterogeneity also linked to this assumption.²⁷

2.4.3 Cross-country estimates

Table 1 shows the outcomes of the panel estimates of Eq.(8) for the full sample. In the first three columns, it reports the certainty equivalence (CE) version of our consumption model (the baseline model) whereas the rest of the table presents the outcomes of the precautionary saving model (for the sake of brevity, proxies of permanent risk computed for $d = 5$ and $d = 10$ years backwards are reported in the main table). For each model, the table reports in the first column the result of the Least Square Dummy Variable (LSDV) specification and in the second and third columns, respectively, the outcomes of the one step (SGMM) and two step (2SGMM) system GMM estimates. A further empirical exercise with permanent risk as predetermined variable is reported in the last two columns (denoted as PSGMM and P2SGMM, respectively, where P stands for pre-determined).

As can be seen in the table, all coefficients are significant and show the expected signs in all panel estimates. As expected, the LSDV coefficients look downward biased than the system GMM ones, whereas the two step GMM estimates are supposed to be more robust due to the expected persistence of consumption and income²⁸. The consistency of the GMM estimates cannot be taken for granted and depends strictly on the validity of the moment conditions used.²⁹ To test this validity, we adopt the Hansen J Test which

²⁷It is worth noting that the new PWT 8.1 (released in 2015) also provides for the first time estimates for the share of labour income in GDP. These are based on a strong set of assumptions related to comparability across time and space as well as on the decomposition of mixed total income earned by self-employed workers. Unfortunately, this new release is not directly comparable with the previous one (it prepares the ground for a new generation of the PWT managed by the University of Groningen). Moreover, it does not provide separate estimates for private, government and investment shares of consumption. While in fact the previous release, and specifically its consumption component, was primarily intended to measure the standard of living across countries, the new generation is meant primarily to measure the productive capacity of an economy (for more details, see Feenstra et al., 2015).

²⁸While naive OLS regressions of the lagged dependent variable are supposed to be positively correlated with the error, biasing its coefficient estimate upward, the opposite is supposed to happen with the LSDV specification. As a matter of fact, the evidence that LSDV coefficients should be considered downward biased with regard to alternative specifications (including GMM) is included by Roodman (2003) in the checks to perform when using System or Difference GMM. The fact that the two sets of coefficients could converge using the two estimation techniques is excluded.

²⁹Unfortunately, as Roodman (2009) clearly states, there appears to be little guidance from the literature on how many instruments is “too many”. Adopting prudent behaviour, we used the *collapse* option to reduce the proliferation of instruments and always checked

2.4 The empirical strategy and cross-country estimates

is robust to heteroskedasticity.³⁰ It actually rejects the null hypothesis of over-identifying restrictions. Furthermore, the Arellano-Bond test for serial correlation in the first-differenced errors at orders higher than one strongly supports the hypothesis of no serial correlation in the first-differenced errors for all our system GMM empirical exercises.³¹

When looking at the coefficients of the certainty equivalence model, it is worth noting that the long-term propensity to consume out of income is less than one for each of the reported model specifications³². It denotes a relatively high sensitivity of consumption to current income and reveals signs of possible violations of the consumption smoothing hypothesis. The consistency of our empirical estimates with permanent consumption theory actually increases when we control for permanent risks (in the main sections of the table we report for the sake of brevity, only permanent risk computed at the most statistically significant time horizons i.e., $d = 5$ and $d = 10$). This consistency means that the consumption smoothing hypothesis seems to hold net of precautionary saving. In other words, our average “representative household” shows risk-averse behaviour and the supposed violation of consumption smoothing highlighted by the certainty equivalence model becomes perfectly rational once we take into account the role of the overall risk that is perceived to be permanent (as highlighted by the significant coefficients for ex-ante risk and the corresponding increase of the long-term propensity to consume out of income). The highly significant negative relationship between permanent risk and per capita consumption, on average and *ceteris paribus*, is thus the main feature of our empirical estimates. This empirical evidence is fully consistent with the theory of precautionary saving and reveals the presence of extra-saving in response to aggregate risk (i.e., when incomes are perfectly pooled across individuals). If this is the case, standard

the validity of the test for subsets of instruments via the difference-in-Hansen test.

³⁰The most common Sargan test has an asymptotic chi-squared distribution only for a homoskedastic error term. It tends to over-reject with heteroskedasticity.

³¹The presence of autocorrelation in the idiosyncratic disturbance term would render some lags invalid as instruments. Of course, full disturbance is presumed to be autocorrelated because it contains fixed effects. Hence, rejecting the null hypothesis of first-order serial correlation in the first-differenced errors does not imply model misspecification because the first-differenced errors are serially correlated even if the idiosyncratic errors are independent and identically distributed (and the GMM estimation procedure is specifically designed to eliminate this source of trouble). It is only rejection of the null hypothesis of no serial correlation in the first-differenced errors at an order greater than one which implies model misspecification. In fact, if some instruments are endogenous to the error term in differences, they become potentially invalid instruments after all (Roodman, 2009).

³²Note that the long-term propensity to consume can be computed as $-\delta_3/\delta_2$, where δ_3 is the coefficient of the lagged per capita income and δ_2 the coefficient of the lagged per capita consumption.

2.4 The empirical strategy and cross-country estimates

certainty equivalence models are actually severely affected by an omitted variable bias. This result, especially in the case of permanent risk computed using a decade as a time horizon, is robust to the various specifications of our empirical model, including the one step and two step system GMM and also when we control for permanent risk to be a predetermined variable in our empirical specification (see the PSGMM and P2SGMM outcomes in the last two columns of both the permanent risk sections in Table 1).

For sensitivity purposes, in Table 2D-4 in Appendix 2D we present the estimated coefficients for permanent risk computed at various time horizons: from $d = 5$ to $d = 15$ (In Table 2D-4 for the sake of brevity, the parameters of the CE components have been not reported since they do not show any significant changes compared with the previous estimates). It turns out that our estimates are robust to permanent risk computed only at some specific fixed time horizons (e.g. $d = 5$ and $d = 10$ or not far from them) and that the magnitude (in the case of $d = 6$ also the sign) of the relationship is not stable across the different time horizons. Both the high significance of the negative relationship between permanent risk and per capita consumption at fixed time horizons (specifically with $d = 10$) and the instability of the same relationship at the other time horizons provides robust empirical evidence in all our estimates and for different econometric specifications. A possible interpretation of this (and food for thought for further analyses) is that it is probably consistent with the average attitude when people look at risk and/or with the standard design of the available risk-mitigating mechanisms. In other words, it seems to hold a strong tendency of computing the optimal consumption under risk looking at the past performance of income risk at some fixed time horizons (especially for $d = 10$) rather than in the continuum. This interpretation would be consistent with our empirical evidence but calls for further investigation.

To give some insights into the evolution of the model over time, we break down the panel by decades too.³³ This also helps to get additional insights into the evolution of the model over time. Table 2 shows these further empirical outcomes. Here for the sake of brevity, the estimated coefficients by decade of the main variables of Eq. (8) are reported only for the CE version of the model, whereas only the coefficients of the various proxies of permanent risk (for $d = 5$ and $d = 10$ and for risk assumed as a predetermined variable which is reported as *permanent risk pred.* in the table) are reported for the corresponding precautionary saving specification of the same model. Also in

³³Going backwards from the last available observation, we set up the following decades: decade 1 (1960-1969); decade 2 (1970-1979); decade 3 (1980-1989); decade 4 (1990-1999); decade 5 (2000-2008). Results for decade 1950-1959 are not available since we cannot observe consumption volatility for d previous periods.

2.4 The empirical strategy and cross-country estimates

this case, with the exception of the first decade, the LSDV coefficients appear to be downward biased than the system GMM ones. Regarding the negative relationship between permanent risk and per capita consumption highlighted for the full period, it turns out to be more significant in the last decade (from 2000 onwards). This looks consistent with the more recent literature that underlines how the relevance and significance of the negative incidence of aggregate risk/macroeconomic fluctuations are actually rising in recent years, on average and *ceteris paribus*.

Acknowledging that lower frequency data are likely to be more robust (see sub-section 2.4.2), as a robustness check for the validity of the estimates, we carry out the same estimates also averaging data over 3-year spans. Unfortunately, this dramatically reduces the number of observations (from about 6,000 to about 2,000 and below 1,500 if we compare the estimates with permanent risk with $d = 10$) and smooths the data reducing the relevance of consumption smoothing. As a matter of fact, the coefficients of lagged consumption and lagged income (whose ratio determines the long-term propensity to consume) are weakly significant in the SGMM specification even in the certainty equivalent specification (columns 2 and 3). Moreover, averages tend to smooth the risk component too. Notwithstanding the above caveats, Table 2D-6 in Appendix 2D shows that the negative relationship between consumption and permanent risk still holds, even if it turns out to be only weakly significant with permanent risk computed over a 10-year time span (when we are actually using less than 1,500 observations.)

As stated by the theory of precautionary saving, income and past consumption levels are sufficient statistics to absorb the most important factors for current consumption (see Appendix 2A) and there are no hints in the theory that suggest heterogeneity in country paths of adjustment to their respective steady state consumption other than via income. On the other hand, we should admit that a number of possible country time variant characteristics may matter as well in our empirical analysis (e.g. consumption distribution; the size of the government sector, etc.). Unfortunately, these statistics are not provided by the PWT and neither are they easily obtainable from other data sources. However, to get some feeling for the relevance of such heterogeneous factors in driving consumption convergence, as a further robustness check, we also run the model by adding a full set of country-specific trends. This is not possible for system GMM estimates since instrument proliferation soon becomes an issue (the instrument count grows extremely large relative to the sample size) but we can run the test using LSDV. As in the main estimates, we should acknowledge these further outcomes as probably being downward biased than the true parameters. Table 2D-7 in Appendix 2D reports the estimated coefficients with country-specific trends. As can be

2.4 The empirical strategy and cross-country estimates

seen in the table, while the estimates turn out to be more robust and the coefficients for income risk decrease slightly in magnitude and significance, the negative relationship still holds.

To control for the presence of heterogeneity in the conditional distribution of per capita consumption according to countries' income, we run the same estimates by also clustering countries by income deciles. Since the estimates by deciles introduce a truncation of the dependent variable that can yield potentially biased estimates, we need to control for this source of sample selectivity (or non-random) bias.³⁴ In this case, we are perfectly aware of the selection process that governs this sample selectivity bias and we can solve the problem by applying a Heckman two-step procedure. This requires us to run a selection equation prior to the main equation which determines, for each income decile, whether the dependent variable is observed (the selection mechanism). This selection equation is a probit equation which includes all the relevant exogenous variables of the main equation plus the value of the per capita real income as the identifying variable, i.e., the variable that determines the selection process into income deciles.³⁵ The selection equation estimates are then used to construct proxies of the inverse of the "Mills ratio" term³⁶. This term is then included in the main equation regressions where only the truncated dependent variable is considered to derive the so-called "selection coefficient" (θ). This coefficient represents the product of the correlation coefficient between the error in the selection equation and the error in the main equation, and the standard error of the main equation. Thus a simple t-test of whether $H_0 : \theta = 0$ is a workable test for sample selectivity bias.

Table 3 shows the empirical outcomes of the estimates by income deciles. Note that here for the sake of brevity (to avoid having too many columns for each decile), for the estimates with permanent risk as predetermined variable we report only the estimated coefficients of the permanent risk (named as "permanent risk pred") at the end of the table. As expected, the selectivity bias cannot be ruled out with high probability in most cases (as witnessed by the strong significance of the estimated coefficients of the inverse Mills ratios). It is worth noting beforehand that the precision of the estimated coefficients is dependent on the density of the points at each decile. In this light, we should

³⁴This is something that is different from the standard censored Tobit model since we only observe the complete regression model after the selection process into income deciles has actually occurred.

³⁵In this case, the Panel Probit technique with country fixed effects is assumed to be unbiased since T is large and n not small. For more details, see Wooldridge (2002).

³⁶It is defined as $\lambda_i = \frac{\phi[x_i'\beta]}{\Phi[x_i'\beta]}$. For more details, see Wooldridge (2002).

2.4 The empirical strategy and cross-country estimates

handle these estimates with care as suggested by a perfect Hansen statistic of 1.000 as well as the apparent absence of selectivity bias for the two extreme deciles. On the other hand, the hypothesis of no serial correlation in the first-differenced errors is not close to being rejected in any of the empirical exercises by deciles.³⁷ The most interesting feature of this further empirical exercise is that precautionary saving behaviour is confirmed, on average and *ceteris paribus*, and this phenomenon is widespread, with some exceptions, across the entire income distribution, poorest deciles included (even if this is not significant for the poorest one).

For sensitivity purposes and to avoid the likely selection bias due to countries' past performances, we report in Table 2D-8 additional estimates by deciles in which countries have been classified according to their income in the first decade of the observed time span (1960-69). This avoids the bias to classify countries as relatively poor and/or relatively rich according to their actual performance during the observed time span rather than their actual economic situation at the beginning of the observed period. This correction is particularly relevant for countries that have followed a strong evolutionary path, e.g. China. The empirical outcomes for these new estimates by income deciles do not substantially differ from the previous ones. Precautionary saving behaviour is still confirmed and it is still widespread across the income distribution, including the poorer countries in the world which actually show, on average and *ceteris paribus*, a significant phenomenon of 'extra-saving' associated with aggregate risk.

To summarise, our empirical long-run cross-country panel exercise shows substantial evidence of a robust negative relationship between permanent risk and per capita consumption. This empirical evidence is widespread across the entire income distribution. However, it is robust for risk computed over specific time horizons and for more recent decades. This empirical evidence is, on the one hand, consistent with the theory that sees consumption fluctuations as optimal responses to risk. On the other hand, it is also consistent with the common concern over a likely "precautionary-investment"/"volatility trap" effect which has been highlighted in the most recent models of consumption under uncertainty (Reis, 2009; Cherif and Hasanov, 2012). This is probably linked to a change in portfolio allocation between risky capital and safe assets with risk-averse agents shying away from risky investment and, possibly, also causes indirect welfare cost by hampering future consumption possibilities (Loayza et al., 2007). In this respect, this empirical evidence implies a per-

³⁷As specified above, the likely absence of serial correlation in the first-differenced errors at an order greater than one is the most common test for the validity of instruments since if some instruments are endogenous to the error term in differences they become potentially invalid (Roodman, 2009).

manent lower smooth path of consumption with permanent negative effects on welfare.

As underlined in Section 2, there is also a debate on the relative magnitude of the welfare cost of risk. In this respect, this work is innovative with regard to the existing literature by proposing a way to look empirically at the cost of volatility on welfare other than via the usual compensation parameters of household preference for stability (see, for instance, Lucas, 1987, 2003 and Reis, 2009). By focusing on the impact of risk on consumption behaviour and the implied changes in portfolio allocation between risky capital and safe assets, we can provide useful insights into the welfare cost of risk. Specifically, we can derive a relative measure of the net contribution of risk on consumption behaviour, on average and *ceteris paribus*, by standardising the variables and derive standardised coefficients. The estimated standardised coefficients of Eq.(8) are reported in Table 2D-5 (for the sake of brevity, only the full sample estimates are reported).³⁸ The relative lower magnitude of the estimated standardised coefficients for permanent risk compared with all the other consumption determinants shows that, in line with the Lucas (1987, 2003) computation, the cost of fluctuations should be perceived to be low in terms of welfare. Its impact in terms of consumption volatility has been approximately equal to half of the overall impact of a change in the short-run propensity to consume.³⁹

2.5 Conclusion

Unlike previous work on the cost of macro volatility, we perform an empirical strategy grounded on the theory of precautionary saving in a long-run pre-crisis period (1950-2009) and wide cross-country setting (147 countries).

Our empirical model estimates a significant negative relationship, on average and *ceteris paribus*, between permanent risk and per capita consumption. This empirical evidence is widespread across the entire income distribution. However, it is robust for risk computed over specific time horizons and for more recent decades.

This conclusion is, on the one hand, consistent with the theory that sees consumption fluctuations as optimal responses to risk. On the other hand, it

³⁸Note that the estimates based on standardised variables do not include the constant term. This is because each standardised variable has a mean of 0 and hence $cons = \hat{\mu}_Y - b_1 * \hat{\mu}_{x_1} - b_2 * \hat{\mu}_{x_2} = 0$

³⁹The impact of standardised coefficients on the dependent variable is assessed as its change in terms of standard deviation induced by a change of one standard deviation of the independent variable.

2.5 Conclusion

is also consistent with a likely “precautionary-investment”/“volatility trap” effect that, in turn, implies a permanent lower smooth path of consumption with permanent negative effects on welfare. Our empirical results are consistent with the previous empirical literature and suggest the need to be aware of a likely omitted variable bias in performing certainty equivalent analyses, i.e., not controlling for the precautionary saving component. However, they cannot refute Lucas’s (1987, 2003) view that the cost of fluctuations should be perceived to be low in terms of welfare implications.

Our empirical evidence provides new insights into the long-standing debate over the costs of fluctuations. It shows that countries - including poorer ones - hold “extra saving”, in a long-run perspective, because of economic fluctuations. This phenomenon is neither transitory nor specific to the current “crisis period”, even if it is increasing over time.

Appendix 2A - Consumption with Constant Absolute Risk Aversion (CARA) Utility

Blanchard and Fischer (1989), Caballero (1990 and 1991), Weil (1990), Guiso et al., (1992), Carroll (2013) among others, assume that agents maximise the expected value of the following time-separable Constant Absolute Risk Aversion (CARA) utility function.

$$\max E_t \left[\sum_{t=0}^{\infty} \beta^t e^{-\rho c_t} \right] \quad (2A-1)$$

where β is a subjective discount rate of consumption (time preference) and ρ is the degree of absolute risk aversion.⁴⁰ Eq. (2A-1) is subject to the following standard budget constraint:

$$w_{t+1} = R w_t + y_{t+1} - c_{t+1} \quad (2A-2)$$

where $R = (1 + r)$ is the interest factor (assumed to be constant); w is individual wealth (w_t is given) and y_t is the consumer's idiosyncratic income. This latter exhibits a random-walk deviation from an exogenously growing measure of permanent income:

$$y_{t+1} = \hat{y}_t + \psi_{t+1} \quad (2A-3)$$

In the perfect foresight version of the model (where $\psi_t = 0 \forall t$), the Euler equation is:

$$e^{-\rho c_t} = R \beta e^{-\rho c_{t+1}} \quad (2A-4)$$

$$1 = R \beta e^{-\rho(c_{t+1} - c_t)} \quad (2A-5)$$

$$R \beta = e^{\rho(c_{t+1} - c_t)} \quad (2A-6)$$

Taking logs:

$$\rho(c_{t+1} - c_t) = \ln(R \beta) \quad (2A-7)$$

$$c_{t+1} = c_t + \ln(R \beta)^{\frac{1}{\rho}} \quad (2A-8)$$

⁴⁰Because of the use of exponential utility in this exercise the degree of absolute risk aversion is assumed to be equal to the degree of absolute prudence.

Starting from Eq.2A-8 let now assume a stochastic environment with permanent income shocks distributed normally, i.e., $\psi_t \sim N(0, \sigma_\psi^2)$. For the sake of simplicity let us assume also $R\beta = 1$. Eq. 2A-8 becomes:⁴¹

$$c_{t+1} = c_t + \frac{1}{2}\rho\sigma_\psi^2 + \epsilon_{t+1} \quad (2A-9)$$

Since the intertemporal budget constraint must hold in every state of the world the expected present discount value of consumption must equal current wealth plus the expectation of the present discount value of income as follows:

$$E_t[PV_t(c)] = w_t + E_t[PV_t(y)] \quad (2A-10)$$

where PV is the present discount value. Thus we first derive the present discount value of consumption as follows:

$$PV_t(c) = c_t + \frac{(c_t + \frac{1}{2}\rho\sigma_\psi^2 + \epsilon_{t+1})}{R} + \frac{(c_t + \frac{1}{2}\rho\sigma_\psi^2 + \epsilon_{t+1} + \frac{1}{2}\rho\sigma_\psi^2 + \epsilon_{t+2})}{R^2} + \dots \quad (2A-11)$$

and its expected value as follows:

$$\begin{aligned} E_t[PV_t(c)] &= c_t + \frac{c_t}{R} + \frac{c_t}{R^2} + \dots + \frac{\frac{1}{2}\rho\sigma_\psi^2}{R} + \frac{2\frac{1}{2}\rho\sigma_\psi^2}{R^2} + \frac{3\frac{1}{2}\rho\sigma_\psi^2}{R^3} + \dots = \\ &= c_t(1 + R^{-1} + R^{-2} + \dots) + \frac{1}{2}\rho\sigma_\psi^2 \sum_{j=1}^{\infty} \frac{j}{R^j} \end{aligned} \quad (2A-12)$$

Since if $R > 1$ then $\sum_{j=0}^{\infty} \frac{j}{R^j} = \left(\frac{R}{(R-1)^2}\right)$, the expectation of the infinite horizon present discount value of consumption becomes:

$$E_t[PV_t(c)] = c_t \left(\frac{1}{1 - \frac{1}{R}} \right) + \left(\frac{\frac{1}{2}\rho\sigma_\psi^2 R}{(1 - R)^2} \right) \quad (2A-13)$$

Then we derive the present discount value of income as follows:

$$PV_t(y) = \hat{y}_t + \frac{(\hat{y}_t + \psi_{t+1})}{R} + \frac{(\hat{y}_t + \psi_{t+1} + \psi_{t+2})}{R^2} + \dots \quad (2A-14)$$

⁴¹Please note that the inter-temporal substitution of consumption (the last term in Eq. 2A-8) takes here the form of additive changes in the level of consumption (while in CRRA is a multiplicative term of the growth rate of consumption).

and its expected value as follows:

$$E_t[PV_t(y)] = \hat{y}_t \sum_{j=0}^{\infty} R^{-j} = \hat{y}_t \left(\frac{1}{1 - \frac{1}{R}} \right) \quad (2A-15)$$

And derive Eq.2A-16 as follows:

$$c_t \left(\frac{1}{1 - \frac{1}{R}} \right) = w_t + \hat{y}_t \left(\frac{1}{1 - \frac{1}{R}} \right) - \left(\frac{\frac{1}{2}\rho\sigma_{\psi}^2 R}{(1 - R)^2} \right) \quad (2A-16)$$

Re-arranging we finally got:

$$c_t = w_t \frac{R - 1}{R} + \hat{y}_t - (R - 1) \frac{\frac{1}{2}\rho}{(1 - R)^2} \sigma_{\psi}^2 \quad (2A-17)$$

Appendix 2B - Decomposition of observed volatility in income innovations

Carroll and Samwick (1997) propose a simple method for decomposing the volatility of income innovations into a transitory and a permanent component. First, they assume that the log of permanent income follows the process below:

$$\hat{y}_t = g_t + \hat{y}_{t-1} + \eta_t \quad (2B-1)$$

where g_t represents growth due to predictable components (m) as follows: $g_t = m_t - m_{t-1}$, and η_t is a shock to permanent income. If we remove the predictable component of income growth as follows: $\tilde{y}_t = \hat{y}_t - m_t$ and $\tilde{y}_{t-1} = \hat{y}_{t-1} - m_{t-1}$, we can rewrite:

$$\tilde{y}_t = \tilde{y}_{t-1} + \eta_t \quad (2B-2)$$

Second, they assume that the log of current income is given by \tilde{y}_t plus a transitory error term:

$$y_t = \tilde{y}_t + \epsilon_t \quad (2B-3)$$

On the assumption that both η_t and ϵ_t are white noise and uncorrelated with each other at all leads and lags, we can derive the d-year income difference as follows:

$$y_{t+d} - y_t = \tilde{y}_{t+d} - \tilde{y}_t + \epsilon_{t+d} - \epsilon_t \quad (2B-4)$$

Substituting Eq.2B-2 into Eq.2B-4 recursively yields:

$$y_{t+d} - y_t = \eta_{t+1} + \eta_{t+2} + \dots + \eta_{t+d} + \epsilon_{t+d} - \epsilon_t \quad (2B-5)$$

Hence, the d-year second moment is

$$var(v_{yd}) = d\sigma_\eta^2 + 2\sigma_\epsilon^2 \quad (2B-6)$$

where σ_η^2 and σ_ϵ^2 are, respectively, the variances of the permanent and transitory shocks to income.

To apply this decomposition method to our analysis, on the assumption of no individual specific growth rates for income other than those predictable, we compute the variance of v_{yd} for each country i as follows:

$$var(v_{yid}) = v_{yid}^2 \quad (2B-7)$$

We then use two v_{yid}^2 of different lengths to estimate the permanent component of the variance of income innovation for each i as follows:

$$s_{\eta_i}^2 = v_{yid}^2 - v_{yid-1}^2 \quad (2B-8)$$

To get also a measure of $s_{\epsilon_i}^2$ it is sufficient to acknowledge that:

$$s_{\eta_i}^2 = ds_{\eta_i}^2 + 2s_{\epsilon_i}^2 - v_{yid-1}^2 \quad (2B-9)$$

and finally yield $s_{\epsilon_i}^2$ as follows:

$$s_{\epsilon_i}^2 = \frac{v_{yid-1}^2 - (d-1)s_{\eta_i}^2}{2} \quad (2B-10)$$

where $E(s_{p_i}^2) = \sigma_p^2$ and $E(s_{\epsilon_i}^2) = \sigma_\epsilon^2$ and σ_p^2 and σ_ϵ^2 are the variances of the permanent and transitory shocks to income, respectively.

Appendix 2C - The derivation of the unconstrained version of the ECM

Starting from the ARDL (1,1) version of the consumption model:

$$c_t = \beta_0 + \beta_1 y_t + \beta_2 y_{t-1} + \beta_3 c_{t-1} + u_t \quad (2C-1)$$

We subtract c_{t-1} on both sides and take into account of the steady state equilibrium by acknowledging that $\beta_2 = \beta(1 - \beta_3) - \beta_1$ as follows:

$$c_t - c_{t-1} = \beta_0 + \beta_1 y_t + [\beta(1 - \beta_3) - \beta_1] y_{t-1} + \beta_3 c_{t-1} - c_{t-1} + u_t \quad (2C-2)$$

$$\Delta c_t = \beta_0 + \beta_1 y_t + \beta(1 - \beta_3) y_{t-1} - \beta_1 y_{t-1} - (1 - \beta_3) c_{t-1} + u_t \quad (2C-3)$$

$$\Delta c_t = \beta_0 + \beta_1 (y_t - y_{t-1}) + \beta(1 - \beta_3) y_{t-1} - (1 - \beta_3) c_{t-1} + u_t \quad (2C-4)$$

$$\Delta c_t = \beta_0 + \beta_1 \Delta y_t - (1 - \beta_3) c_{t-1} + \beta(1 - \beta_3) y_{t-1} + u_t \quad (2C-5)$$

Chapter 3

Essay 3 - Trade openness and vulnerability to poverty in Vietnam under *Doi Moi*

This Essay follows up the existing poverty assessments of trade liberalisation in Vietnam under *Doi Moi*. It looks specifically at the relationship between trade liberalisation and vulnerability to poverty. To this end, it first applies, a VEP framework to six recent living standard surveys in Vietnam (covering the period 1992-2008) to assess the presence of heterogeneity of vulnerability to poverty across industries clustered by different degrees of “trade exposure” and their evolution over time. Second, it assesses the relative influence of *ex-ante* versus *ex-post* factors on consumption levels and variability, overall and by trading industries. The following results are obtained: i) a downward trend in vulnerability to poverty in Vietnam together with an increased share of its stochastic (risk) determinant; ii) a relative increase of the percentage of vulnerable people in the relatively higher “trade-exposed” groups of industries; iii) the higher relevance of the *ex-ante* stochastic (risk) component in the higher “trade-exposed” group of industries. The above results are key for policymaking. They highlight a link between trade openness and risk-induced vulnerability as well as the need to target vulnerability to poverty even in a trade liberalisation scenario characterised by decreasing poverty.

Keywords: trade openness, vulnerability, poverty, risk, consumption behaviour, Vietnam.

JEL: F14, O12, D12, C31

3.1 Introduction

Following the so-called “Asian option” of transition, from the early 1990s Vietnam adopted the *Doi Moi* (renovation) process, a combination of liberalisation, stabilisation and structural reforms. Within the liberalisation component, Vietnam experienced two main waves of trade liberalisation, one in the 1990s and a second in the 2000s (Coello et al., 2010). The first wave lasted from the initial opening of the country until approximately 2001 and foresaw the total abolition of trade licences and the removal of most quantitative restrictions (Than, 2005). The second wave - still in place - includes the full involvement of the country in the world network of reciprocal trade agreements (both multilateral, see the WTO accession in January 2007, and bilateral, see the agreements signed with the USA in 2001 as well as the FTA negotiations launched with the EU in 2012).

An extensive empirical investigation on trade liberalisation and poverty dynamics in Vietnam has been carried out to date (Irvin, 1997; Liu, 2001; Fritzen, 2002; Jenkins, 2004; Nadvi et al., 2004; van de Walle and Cratty, 2004; Jensen and Tarp, 2005; Nguyen and Ezaki, 2005; Fujii and Roland-Holst, 2007; Niimi et al., 2007; Abbott et al., 2009; Heo and Doanh, 2009; Coello et al., 2010). Empirical analyses consistently highlight the increased importance of international trade in the Vietnamese economy as well as the positive correlation between trade liberalisation, growth and poverty reduction.¹

However, the above analyses have focused mainly on the first sub-period, when the process of liberalisation was still restricted and subject to trade licences. Moreover, they do not provide any clue to the relationship between openness and vulnerability to poverty. This is because they generally overlook the possible impact of the opening-up process on households’ exposure to risk as well the role of trade openness as one of the possible channels of risk.

Following on from the existing debate on vulnerability induced by trade openness (see Essay 1), this work aims to overcome the above knowledge gaps, starting with a preliminary and workable step: assessing the presence

¹Critics also highlight the relatively high concentration of poor households near the poverty line during the 1990s as a likely explanation for the pro-poor nature of growth in Vietnam. They also highlight the persistence of a high poverty gap in rural areas, in the Northern Mountain and the inland Central Highland regions as well as increased inequality throughout the country, resulting in an extensive urban-rural division, with the richest 20 per cent of the population living in urban areas (Heo and Doanh, 2009). Furthermore, trade openness seems to have promoted a distributional impact within the rice sector too, further penalising the poorer small net producers (Coello et al., 2010). Last but not least, 80 per cent of the poor are still living (and working) in rural areas.

of heterogeneity in households' vulnerability according to the relative degree of trade exposure of their sector of employment. Of course, the presence of significant differences in vulnerability patterns by trading sector does not provide information on the nature of the foreign risks and/or their channels of transmission to household welfare which is outside the scope of this empirical exercise. Moreover, because of the lack of panel data, our analysis is not able to directly control for cross-sectional household heterogeneity or for measurement error and their evolution over time. The problem is that the cross-sectional variation in vulnerability to poverty across the various trade-exposed sectors can actually be driven by a number of factors other than risk (e.g., differences in household characteristics across sectors due to self-selection) that are unobservable to the researcher.

Acknowledging the above empirical constraints, the added value of this analysis lies in taking advantage of the full set of available rounds of household surveys in Vietnam to give a careful interpretation of the cross-sectional evidence of the relationship between household vulnerability and trade openness in "trade-related" industries. Specifically, it is argued that the assessment of an increasing negative relationship between the stochastic component of income and consumption in the case of households involved in the more exposed trading sectors can only reasonably be interpreted as related to risk. Conversely, supposing that the above relationship is not due to risk - but to households' unobservable heterogeneity - it would imply a partial revision of the assumed benefits from trade openness, which is worth investigating too.

The contribution of this paper is twofold: using six living standard surveys in Vietnam (covering the period 1992-2008), we first assess the percentage and the evolution of vulnerable people across the different sectors of the economy organised according to their relative degree of trade exposure; second, we provide an assessment of how much of the households' consumption variation (which is at the core of vulnerability analysis) can be explained by its stochastic *ex-ante* component, namely the variance of income within trade-exposed defined groups, as well as by actual income shocks, defined as the component of income variation unexplained by observables.

Our results are the following: a downward trend in vulnerability to poverty in Vietnam together with an increased share of its stochastic (risk) determinant; a relative increase in the percentage of vulnerable people in the relatively more trade-exposed sectors; iii) the non-decreasing relevance (both in terms of net mean contribution on expected average and variance of household consumption) of the *ex-ante* stochastic (risk) component in the higher "trade-exposed" groups of industries. The above results are key for policymaking. They highlight a link between trade openness and risk-induced vulnerability as well as the need to target vulnerability to poverty even in a

3.2 Trade and vulnerability to poverty: literature review and conceptual framework

trade liberalisation scenario characterised by decreasing poverty.

The paper is organised as follows: section 2 reviews the literature and presents the conceptual framework; section 3 provides details on the measurement of vulnerability to poverty; section 4 presents the empirical results and section 5 concludes.

3.2 Trade and vulnerability to poverty: literature review and conceptual framework

Notwithstanding differences in conceptual approaches and empirical methods, the literature on trade liberalisation and poverty dynamics in Vietnam has reached consensus on the following issues: price liberalisation has had a great impact on agricultural households and consumers since 1986 (Nimi et al., 2007) with poverty reduction figures for rice net producers better than for rice net consumers (Heo and Doanh, 2009); trade liberalisation has been beneficial to the poor thanks to the highly labour intensive structure of the Vietnamese exports;² the negative effects of trade liberalisation occurred mainly in coffee production (Ha and Shively, 2008).

However, a key issue remains unanswered: Has trade openness magnified households' exposure to risk and raised vulnerability to poverty? The topic is currently hotly debated by practitioners, whereas it is largely ignored by trade literature (see Essay 1). In principle, trade can magnify risks in two ways: by changing the riskiness of existing activities, for instance, by altering the weight of foreign compared with domestic shocks faced by the economy, or by changing the emphasis among the different activities households engage in such as, for example, switching from subsistence food crops to cash crops (McCulloch et al., 2001). Hence, trade openness could alter households' optimal portfolios so that their current ones become sub-optimal *ex-ante*.³ This is especially true for the poor, due to their poor ability to take advantage of the positive opportunities created by trade reforms, their weak capabilities to insure themselves from adverse impacts and, possibly, the lack of information on the risks associated with the new activities induced by openness (Winters

²Abbott et al. (2009) claim that the poverty impacts of trade reforms in Vietnam are even larger than those anticipated by existing model predictions, because of the intrinsic limitations of the most common applied methods and because they generally overlook the fact that institutional rather than tariff reforms have been the main driving factor behind recent development in Vietnam.

³Of course, *ex-post*, a household may lose out because of unlucky realisations. Hence, increases in observed poverty can be consistent with *ex-ante* improvements in welfare if households trade higher mean incomes for higher variances (Winters et al., 2004).

3.2 Trade and vulnerability to poverty: literature review and conceptual framework

et al., 2004). Thus, they suffer the costs of trade reforms without reaping any compensating benefits in the form of higher average earnings (see Morduch, 1994). This, together with the presence of risky assets (Elbers et al., 2007) may explain *ex-ante* their unwillingness to pursue high average returns linked to the different activities opened up by trade reforms, resulting in poverty traps (Carter and Barret, 2006; Dercon and Christiaensen, 2011). Moreover, the poor can be less able to protect themselves from the adverse effects of a new set of man-made foreign shocks and incentives. This is because traditional mechanisms may not work as well as in the pre-liberalisation scenario, hampering people's standard management strategies (Dercon, 2001; Tesliuc and Lindert, 2004). Trade openness can also affect government ability to adopt price stabilisation policies and/or contribute to the elimination of institutions or policies aimed at smoothing domestic prices (Winters, 2002; Winters et al., 2004). In all the above cases, trade openness can have an impact on households' optimal portfolios and, eventually, lead to net welfare effects that are less positive than expected in the long run (Winters, 2002; Winters and al., 2004; Calvo and Dercon, 2007a).

This issue, though very relevant, has been largely overlooked by the empirical literature on trade because it implies the capacity to assess the counterfactual situation, i.e., the unobservable level of consumption that would have prevailed in the absence of risk, net of the mean effects generated by trade. Looking at consumption behaviour as a key behavioural tool in explaining households' choices under risk, in our analysis we assume that vulnerability passes through a deviation from a smooth path of consumption. In other words, we assume that the strategies households employ both to mitigate risks (that is, risk-induced *ex-ante* changing behaviour, Elbers and Gunning, 2007; Giles and Yoo, 2007; Jalan and Ravallion, 2001) and cope with shocks (Coate and Ravallion, 1993; Udry, 1994; Townsend, 1994, 1995; Besley, 1995; Morduch, 2002) can be costly in the short run even if the overall impact in the long run is net beneficial (Ravallion 1988; Morduch 1994; Dercon, 2005). Moreover, we assume these costs to be diversified in terms of consumption behaviour, with the *ex-ante* risk-induced component of vulnerability considered a proper measure of vulnerability.

By decomposing vulnerability into its *ex-ante* and *ex-post* components, we test whether differences in the *ex-ante* component across groups can be associated with different degrees of trade exposure. While, in fact, incomes from non-traded sectors are mainly affected by domestic risks (for example, bad weather, crop failure, livestock diseases, etc.), people engaged in import- and export-related sectors are also supposed to face foreign markets risks (for example, international price fluctuations, exchange rate fluctuations, etc.). We do not really know whether or not domestic and foreign risks are posi-

3.3 Measuring trade-induced vulnerability

tively or negatively correlated (the empirical evidence on this has been quite inconclusive, McCulloch et al., 2001). However, it is reasonable to expect a certain degree of risk heterogeneity associated with the heterogeneity of households' trade exposure. For instance, in the Vietnamese context, poor households in the midst of trade reform have two options in principle: i) rely, with regard to ongoing trade reforms, on conservative choices (for example, subsistence farming) as a main risk management strategy: this choice could help to insulate them from trade-related risks, but leaves them vulnerable to pre-liberalisation ones (for example, natural ones), possibly taking them into a cycle of poverty; ii) carry out progressive choices⁴ (for example, moving to export crops), with an expected increase in mean income as well as in income variance. Thanks to this choice they could climb out of poverty, but remain vulnerable to both pre- and post-liberalisation risks. As a result, these two categories face different kinds of risks and are forced to apply different risk management strategies as well as to rely on different risk coping strategies when shocks occur. As a result, they will probably show different behavioural choices *ex-ante* and different welfare impacts *ex-post*.

3.3 Measuring trade-induced vulnerability

In this empirical exercise, we first apply the most common measure of vulnerability⁵, i.e. the "Vulnerability to Expected Poverty" (VEP) method (Pritchett et al., 2000; Christiaensen and Subbarao, 2005; Chaudhuri and Datt 2001; Chaudhuri et al., 2002 and Chaudhuri 2003; Kamanou and Morduch, 2004; Gunther and Harttgen, 2009). The reason is twofold: i) it helps us derive a vulnerability measure using the single rounds of the available cross-sectional household data for the period 1992-2008; ii) it is consistent with existing poverty analyses since it provides results in terms of expected values of the common Foster-Greer-Thorbecke (FGT) class of decomposable poverty measures.

The VEP method looks at vulnerability as the probability that a household will fall into poverty in the near future.⁶ To this end, it adapts the standard FGT index (Foster et al., 1984) to a stochastic environment and takes its expected value as follows:

⁴The term progressive is used here for ongoing trade reforms.

⁵A first taxonomy of the main methods applied in vulnerability analysis has been provided by Hoddinott and Quisumbing (2003). A slight update to this is provided in Appendix 1.5.

⁶Further details on the computation of this measure for different time horizons will be provided later on.

3.3 Measuring trade-induced vulnerability

$$V_{\alpha,ht} = F(z) \int_0^z \left(\max \left\{ 0, \frac{z - c_{h,k}}{z} \right\} \right)^\alpha \frac{f(c_{h,k})}{F(z)} dc_{h,k} \quad (1)$$

where c_h is household consumption; z is the standard poverty line; $F(\cdot)$ and $f(\cdot)$ indicate, respectively, the cumulative distribution and the density function of consumption at time k ⁷. Since we rely on the headcount measurement of poverty ($\alpha = 0$), our VEP measure is reduced to the probability that the household will experience poverty, i.e. $V = F(z)$.⁸ The distribution F is taken as given and reflects both household exposure to shocks (idiosyncratic or covariant) and the ability to cope with them. More specifically, the VEP index measures "vulnerability to poverty" as the probability that household h will be poor, as follows:

$$V_{\alpha,ht} = Pr(\ln c_{h,k} < \ln z | X_{ht}) = \Phi\left(\frac{\ln z - \ln \hat{c}_{h,k}}{\sqrt{\hat{\sigma}_{h,k}^2}}\right) \quad (2)$$

where Φ is the cumulative function of the standard normal (see Appendix 1.5 in Essay 1 for additional details on the VEP measure) and k is the number of years in the future of the chosen time horizon.

The VEP method also provides a first decomposition between "poverty-induced" vulnerability and "risk-induced" vulnerability (Gunther and Harttgen, 2008). The first component refers to vulnerable households with estimated expected mean consumption below the poverty line (i.e., vulnerability is mainly driven by permanent low consumption prospects); the second refers to vulnerable households with estimated expected mean consumption above the poverty line, but high estimated variance of consumption (i.e., vulnerability is mainly driven by consumption volatility). However, VEP does not model risk explicitly, but assumes that the observed inter-household distribution of consumption at a point in time represents the future distribution of consumption across states of the nature for each household.

The VEP method suffers various shortcomings, some related to problems caused by the FGT measures of poverty and others specific to the stochastic nature of the analysis and underlying assumptions. The main shortcoming is given by the fact that it, generally speaking, overlooks the key role of the

⁷Eq. 1 is obtained by multiplying the expected value of the poverty index by $F(z)/F(z)$. For more information on the derivation procedure of Equation 1, see Christiaensen and Boisvert, 2000.

⁸The majority of works rely on this choice (Christiaensen and Boisvert, 2000; Pritchett et al., 2000; Chaudhuri and Datt, 2001; Chaudhuri et al., 2002), but there are also some VEP applications that look at the depth of poverty ($\alpha = 1$) and at the spread of its distribution ($\alpha = 2$) (see, for example, Ravallion, 1988).

3.3 Measuring trade-induced vulnerability

behavioural response to risk. Practically speaking, a household that adopted complete self-insurance mechanisms at the cost of lower mean welfare would be registered as unaffected by risk, hence attributing its low level of welfare entirely to non-stochastic components of poverty. In other words, it produces a structural underestimation of the risk component of vulnerability with a parallel overestimation of its poverty component, leading to biased outcomes (Elbers and Gunning, 2003). Moreover, it does not provide any clue to distinguishing whether vulnerability is properly generated *ex-ante* (mainly linked to a lack of mitigating risk strategies) or *ex-post* (mainly associated with a lack of coping mechanisms).

To avoid this shortcoming and take into account the simple evidence that risk affects *ex-ante* households' savings decisions and thereby their consumption level, following on from Elbers et al. (2007), Elbers et al. (2009) and Carter and Ikegami (2009), we complement VEP outcomes with an empirical test on the relative importance of the various determinants of consumption behaviour under risk to infer the relative importance of the various components of vulnerability (non-stochastic, risk induced and shocks). Following Achen (1982), here we explore "importance" both in the sense of significant potential effects (i.e., the net mean contribution of each consumption behaviour's determinants) and in terms of dispersion effects (i.e., the net contribution to explaining the variance of consumption behaviour).

To this end, here we follow a consolidated literature that looks at the household's consumption in any period as determined by wealth, current income, uncertainty over future income as well as behavioural responses to cope with and manage risks (Deaton 1992; Browning and Lusardi, 1996; Chaudhuri, 2003; Dercon, 2005). We also follow the previous literature on poverty in Vietnam (Glewwe et al., 2002; Minot and Baulch, 2005; Niimi et al., 2007; Justino et al., 2008; Cuong et al., 2010; Nguyen and Winters, 2011) that assumes that all these factors are functions of a variety of observable household characteristics such as demographics, education and occupation, and depend on a set of characteristics related to the surrounding economic environment. To isolate the separate impact of the ex-ante permanent risk, we follow the same precautionary saving framework introduced in Essay 2 (Carroll, 2001; Kimball, 1990; Caballero, 1990; Deaton, 1992) and filter out the ex-ante permanent risk from possible measurement errors by applying the same decomposition method as Carroll and Samwick (1997). It is worth recalling here that this empirical exercise cannot be considered a proper exogenous test for the precautionary saving theory because of the lack of panel data. This is an unavoidable empirical constraint. Thus, we should assume the empirical outcomes of the risk channel as upper bounds of the true impacts (by the way, likely endogeneity in the other determinants of

3.3 Measuring trade-induced vulnerability

current consumption would actually soften the relevance of the risk channel thus lowering our upper bound reference). Furthermore, in the final part of the empirical analysis, we will demonstrate the likely inconsistency of the alternative hypotheses.

This follows the following simple linear econometric specification:⁹

$$c_{ht} = \alpha + \beta X_{ht} + \varphi V_t + \epsilon_{ht} \quad (3)$$

where c_{ht} is the log of per capita consumption of household h at time t ; X_{ht} and V_t are two vectors of exogenous variables which control, respectively, for the household's and village's characteristics; ϵ_{ht} is the error term. While the non-random consumption is assumed to be simply equal to the predicted value of the Eq. 3, to estimate its stochastic component we need to identify an observable and exogenous proxy of risk. The most commonly applied method of extracting parsimonious information on risk from data is to calculate the variance of innovations to income. This is usually performed (Carroll and Samwick 1997, 1998; Hubbard et al, 1994; Gourinchas and Parker, 2002; Jalan and Ravallion, 2001; Meghir and Pistaferri, 2004; Storesletten et al., 2004) by calculating the variance of the residuals (μ_{ht}) of an income equation such as the following:

$$y_{ht} = \tau + \gamma Z_{ht} + \pi V_t + \mu_{ht} \quad (4)$$

where y_{ht} is the log of per capita income, Z is similar to X in Eq. 3 with the inclusion of the occupation characteristics¹⁰, and V is the same set of commune characteristics as in Eq. 3. We also insert dummies for trade categories in the income regression. We believe in fact that it is more plausible to assume that households actually know which group they are in and hence that they make reference to their group average and not to the overall average income (i.e., they do not consider the inter-group differences in income as risk as implicitly assumed if we do not control for trade group dummies in the income regression). Moreover, in each round of observations, we compute the variance of the income innovations by “trade-related” groups as follows:

$$\sigma_{ygt}^2 = \sum_{h=1}^n (\mu_{hgt} - \bar{\mu}_{gt})^2 / n \quad (5)$$

⁹Here we are implicitly assuming that consumption is log normally distributed. Brown- ing and Lusardi (1996) provide an excellent survey of the empirical test on precautionary saving based on linear regression.

¹⁰The occupation characteristics are assumed to influence consumption behaviour only through income.

3.3 Measuring trade-induced vulnerability

where μ_{hgt} indicates income innovation of household h in trading group g in round t of observations. Following Skinner (1988), Guiso et al. (1992), Blundell and Stoker (1999), Banks et al., (2001) and Giles and Yoo (2007), we further rescale it by a specific factor (π_{ht}) based on household expected wealth. In particular, consistent with the adoption of the CRRA utility function, we assume that poorer individuals are more responsive to changes in risk, scaling up the variance of income innovations by the square of the ratio between current household's income and expected lifetime wealth.¹¹ Our final proxy for income innovation is thus the following:

$$\sigma_{yht}^2 = \pi_{ht} \sigma_{ygt}^2 \quad (6)$$

where $\pi_{ht} = \left(\frac{y_{ht}}{\hat{w}_{ht}} \right)^2$ and \hat{w}_{ht} is a measure of the expected wealth. As well as its theoretical foundation, the scaling term has the additional advantage of allowing us to obtain a risk measure that is specific to each household in the sample in each period, further differentiating risk exposure across the households belonging to the same trading group.

It is worth noting that, since the lack of panel data prevents us from exploiting the time dimension, here we are assuming the unexplained component of income in cross-section data in Eq. 4 to proximate stochastic innovation. While it is true that the unexplained component probably also contains non-stochastic unobservables as well as measurement error, it is not necessarily true for the variances of income innovations within sub-samples of households grouped according to their trade openness position. We will come back to this important caveat later on when looking at the empirical outcomes.

To provide a separate measure of the impact of idiosyncratic shocks on consumption in addition to the *ex-ante* impact of risk (the former influenced by the available coping mechanisms of the households, the latter by their mitigating strategies), we rely on objective measures based on income realisations. Considering that the self-reported measures of idiosyncratic shocks can be biased by subjective perceptions, we calculate the income shock variable using an objective measure such as the ratio between the household residual from Eq. 4 and the predicted level of log income, as follows:

¹¹According to Skinner (1988) and Guiso et al (1992), the exponent of the scaling factor measures the sensitivity to the level of expected wealth exhibited by the reaction to uncertainty. If the exponent is more than zero, the effect of risk on consumption declines with the household's resources and the decline is faster the higher the value. Usually, the adopted value is two and this is why we use the square of that ratio.

$$\zeta_{yht} = \frac{\hat{\mu}_{ht}}{\hat{y}_{ht}} \quad (7)$$

In order to obtain true idiosyncratic shocks, we insert a series of provincial dummies into the Eq. 4 which allow us to "clean" the residual of its covariate component. Finally, we disentangle the positive (ζ_y^+) from the negative (ζ_y^-) shocks in order to consider the possibility that the households are credit constrained and thus unable to fully smooth their consumption in the event of negative shocks.

The last step is to exploit the proxies for risk and shock to retrieve our *ex-ante* and *ex-post* consumption counterfactuals, as follows:

$$c_{ht} = \alpha + \beta X_{ht} + \varphi V_t + \theta_1 \sigma_{yht}^2 + \theta_2 \zeta_y^+ + \theta_3 \zeta_y^- + \epsilon_{ht} \quad (8)$$

3.4 The empirical analysis

Data

Because of the lack of panel data covering the entire period under analysis, our empirical exercise relies on cross-sectional data for the following years: 1992, 1998, 2002, 2004, 2006 and 2008. Data come from two different sets of Vietnamese household surveys (VLSS and VHLSS). The VLSS was undertaken in the period 1992/93 using a sample of 4,800 households, of which 4,000 were re-interviewed in 1997/98, out of a sample of 6,000 households in total. The VHLSS collected information from a new sample of 29,530 households in 2002; 9,188 in 2004; 9,189 in 2006 and 2008. Unfortunately, as reported by Pham and Reilly (2007) and Le and Booth (2010), the sampling frame for VHLSS differs substantially from that of VLSS: whereas VLSS used the 1989 Population Census, the VHLSS 2002 exploited the Population and Housing Census from 1999. As a result, while there are short panel samples from the last waves, no household was re-interviewed between the VLSS and the VHLSS and, generally speaking, a comparison between VLSS and VHLSS rounds is not possible.¹² It is generally agreed that VHLSS data can be considered to be of higher quality than VLSS and provide legitimate nationally representative household data based on stratified random samples. However, it has been demonstrated that households residing in VHLSS communes were on average better off in 1999 and are still better off in 2009

¹²As a matter of fact, we register a clear jump in the magnitude of our empirical estimates from VLSS to VHLSS rounds.

3.4 The empirical analysis

than the households living in non-VHLSS communes since durable goods such as televisions, motorbikes, phones, refrigerators and even computers are more widespread in the VHLSS-communes (for more details, see Hansen and Dang Le, 2013). If this is the case, it implies an overall downward bias of our subsequent estimates of “upper bound” vulnerability (our proxies of wealth in the denominator of the scaling factor tend to be overestimated) with no consequences in relative terms.

The variable used for consumption is the real per capita food and non-food expenditure in the past 12 months re-adjusted by price indexes of regions and months. Food expenditure includes information on both market purchases and consumption from home production of 58 items while the non-food expenditure collects information on 32 items such as fabric, clothing, blankets, pillow, tailoring or laundry service, shoes, nylon sheeting, electrical equipment, etc. Poverty lines for computing vulnerability are expressed in Vietnamese dong as follows: 1,160,000 for 1992; 1,790,000 for 1998; 1,915,000 for 2002; 2,070,000 for 2004; 2,559,000 for 2006; 3,360,000 for 2008.¹³ The variable used for household real per capita income, has been derived by aggregating income into six major categories: income from crops, income from agricultural sidelines, household business income, wage income, gifts and remittances, and other residuals sources of income. Income from crops is net income (gross revenue minus current expenditures) from rice; other cereals, vegetables, and annual crops; industrial crops; fruit crops; and crop by-products such as straw, leaves, etc. Agricultural sidelines include livestock and other animal products, agricultural services, forestry services, hunting, trapping, and domesticating wild animals, and aquaculture. Household business income is net income from non-agriculture, non-forestry, and non-aquaculture businesses run by the household and includes the processing of agricultural, forestry and aquaculture products. Wage income includes salary or wage payments plus additional payments such as holiday contributions, social insurance payments, etc. for all jobs held by individuals during the past 12 months. Gifts and remittances include payments from both domestic and overseas sources. Finally, “other” residual sources of income include items such as government transfers and earned interest as well as rental income from land and housing. The income variable has been also re-adjusted by price indexes of regions and months.

We cannot avoid possible measurement errors for these key variables. However, when errors are mean zero random errors and the variable with er-

¹³For the regional deflators, we use the indices provided by the GSO in the VHLSS. We also replicate the same exercise using the different set of regional deflators provided by Brian McCaig and the results do not change significantly.

3.4 The empirical analysis

rors is used as a dependent variable, as in our case, it is well known that those errors will not cause estimation bias.¹⁴ Furthermore, as suggested by Nakata et al. (2009), measurement errors in retrospective expenditure seem to be systematically related to household size. This suggests that the inclusion of household size as one of the control variables in our regressions contributes to mitigating biases arising from measurement errors in consumption.

The set of covariates used for our consumption estimates includes household characteristics (such as characteristics of the head of household, i.e., linear and quadratic age, marital status, sex, linear and quadratic terms of family size and number of children); education achievements (primary, secondary, upper secondary, technical/vocational, university) as well as village-level infrastructure characteristics (such as the presence of roads, water pipelines, public transports, urban/rural environment). We also include province dummies to control for spatial heterogeneity.

As regards the measure for expected wealth in the denominator of the scaling factor, while it is widely recognised that living standards are determined by a multitude of factors, consumption expenditure remains the most popular measure in low- and middle-income settings. As a matter of fact, previous empirical analyses that use scaling factors (Banks et al., 2001; Giles and Yoo, 2007) replace expected wealth in the denominator of the scaling factor with the observed level of consumption. However, the presence of period t consumption in the scaling term makes it likely that errors in the measurement of this term will be correlated with errors in the measurement of the dependent variable (Giles and Yoo, 2007). To this end, Banks et al., (2001) and Giles and Yoo (2007) use lagged observed consumption in the scaling term in their estimates (as we will do in Essay 4). Since in this exercise, we cannot rely on panel data, alternative strategies to avoid endogeneity bias in the estimates should be taken into account. In a popular work, Filmer and Pritchett (2001) suggest that asset indices are as reliable as conventionally measured consumption expenditure as a proxy of household living standards. Following this approach, two alternative strategies are tested to proxy for wealth (the denominator) in the π term used in eq. 6. First, we use the current value in thousand dong of the households fixed assets and durable goods. VLSS and VHLSS collect the current value (at the time of interview) of about 59 goods not considered in the household expenditure plus the value of dwelling. Table 3A-2 in Appendix 3A provides the details on these assets and durable goods whereas Tables 3A-3 and 3A-4 report the main descriptive statistics of the final variable overall and by

¹⁴In contrast, when errors are correlated with independent variables or involve a mean-reverting pattern, bias in estimation will arise (Gibson & Bonggeun, 2007).

3.4 The empirical analysis

trade groups. Since the adoption of a price index could determine spurious correlation with the LHS variable, which is deflated too, both income and assets in the scaling term are reported in current values.

Second, as an alternative strategy, to prevent any possible bias due to price influence and handle the vexing problem of choosing appropriate weights, similarly to what has been done by Povel (2015), we proxy the expected wealth in the denominator of the scaling factor using the linear combination of the principal component factors of a sub-set of housing characteristics and physical land availability. Unfortunately, this approach can only be used for the VHLSS dataset since in the case of the VLSS rounds, the use of this index dramatically reduces the number of observations because of the high number of missing values. Table 3C-2 in Appendix 3C reports the list of the housing characteristics used in the principal component analysis and some descriptive statistics. Table 3C-3 reports the set of linear coefficients (i.e., factor loadings) of the first two common factors (i.e., those factors with eigenvalues greater than one). To improve the interpretability of the retained factors we applied the standard orthogonal varimax rotation (Kaiser 1958). Rotating the factors means re-expressing them to maximise their differences (i.e., so that loadings on a few variables are as large as possible and loadings on the rest of the variables are as small as possible). We have this freedom to re-express the factors because of the inherent indeterminate nature of the factor model (e.g., if z_1 and z_2 are two factors, then $z_1 + z_2$ and $z_1 - z_2$ are equally valid solutions). The orthogonal rotated factor loadings are every bit as good as the original loadings. As a matter of fact, if we plot the rotated factor loadings, as in Fig. 3C-1, their interpretation appears to be straightforward: factor 1 gathers the housing characteristics whereas factor 2 focuses on property, land and area availability.

To group households according to the trade openness of their sector of specialisation, since VLSS and VHLSS surveys do not relate production and external trade, we acknowledge here the work done by Coello et al. (2010). They matched the ISIC code of any sector with the SITC classification used in trade data and classified sectors as follows: export manufactured goods; import competing manufactured goods; non traded services; agriculture. A further breakdown of agricultural sector is also provided, as follows: rice (considered separately because of its special status); main export agricultural products, other export agricultural products, import-competing crops and subsistence crops. This allows us to come up with eight trade-related production sectors (see Table A.1 for details on the surveyed industries included in each sector).¹⁵ Table A.2 shows the main characteristics for each

¹⁵The classification of industries as net exporters or net importers is made according

3.4 The empirical analysis

production group across time in terms of mean consumption, income, assets and poverty levels.¹⁶ It shows that the vast majority of sampled households is involved in rice production where mean income and consumption are significantly lower than in the other sectors (with the relevant exception of import-competing crops in 2008). Generally speaking, people involved in non-farm activities are on average richer than farmers. Among the non-farm activities, the highest mean income and consumption levels in almost all rounds of observations are registered in non-traded services followed by import-competing manufacturing. However, in 2008, both farm and non-farm exports actually increased their income and consumption levels. A relative lower incidence of poverty in non-farm sectors compared with the farm ones should also be noted as well as a relatively strong decrease of its incidence in non-traded farm activities (covering, however, a limited range of sectors and a small percentage of the total workforce). Generally speaking, the incidence of poverty seems to be structurally lower in non-farm activities than in farm ones with the relevant exception of farm main-exports and non-traded crops.

Vulnerability by trade-related sector in Vietnam

Table 1 adds new pieces of information to the standard picture of poverty and trade liberalisation in Vietnam under *Doi Moi*, by reporting the vulnerability rates (both the overall VEP rate and the risk-induced VEP sub-component) for each round of household data alongside the poverty rates (both those computed from the survey and those reported by the Vietnam General Statistics Office, GSO). Following Chaudhuri (2003) in this empirical exercise we have considered a household vulnerable if its probability to register a consumption below the poverty line is higher than 0.50. Appendix 3B shows how vulnerability rates change along with changes in the probability thresholds and gives details of the VEP estimation procedure. It is worth noting that these are cross-sectional measures of vulnerability. They should be seen as “snapshots” of the expectation to be poor “in the near future”. As common practice, in this exercise we consider households as vulnerable if they show a probability higher than 0.50 to fall into poverty at least once in the following two years.¹⁷ It is worth noting that *ex-ante* vulnerability

to the average trade flows in 2002. For additional details on the procedure adopted, see Coello et al. (2010).

¹⁶To group the households, we used the characteristics of the head of the family. We also performed the same exercise according to the occupation status and sector of activity of the majority of household members. The outcomes do not change significantly.

¹⁷To make clear-cut computations on a specific number of years in the future, a common procedure is to compute vulnerability as one minus the probability of no episodes of poverty times the number of years of the chosen time horizon in the future (k), as follows:

3.4 The empirical analysis

and *ex-post* poverty should be viewed as different statistics: while we can compare their evolution over time, we cannot draw any cross comparisons between them.¹⁸ At first sight, it is evident from Table 1 that there is a decreasing trend in both poverty and vulnerability rates. The percentage of vulnerable people decreased from around 56 per cent of the total population in 1992 to 8.3 per cent in 2008. However, the table actually shows a roughly constant path of the share of the risk-induced component of vulnerability (i.e., the component of vulnerability associated with a high estimated variance of consumption, but expected consumption above the poverty line) after an initial drop at the eve of the liberalisation process (between 1992 and 1998). During the period 1998-2008 it never fell below the threshold of 31 per cent of the overall VEP. As we will see below, this is a significant issue that needs careful investigation.

Table 1: Vulnerability and Poverty in Vietnam (1992-2008)

	1992	1998	2002	2004	2006	2008
Poverty Rate in the Survey (%)	55.21	29.89	27.99	19.44	15.33	16.40
Poverty Rate (%) GSO	58,1	37,4	28,9	19,5	16.00	14,5
VEP Rate (%)	56.11	21.50	18.26	10.77	7.06	8.31
Risk-induced VEP (% vulnerable)	18.74	33.73	30.99	31.24	32.64	31.06

It is now time to undertake the most difficult task in our analysis: investigate the presence of a likely relationship between risk-induced vulnerability and trade liberalisation in Vietnam. The simple evidence that the two phenomena coexist under *Doi Moi* cannot be the only argument in favour of a direct link between the two. At the same time, this coexistence makes the effort worthwhile. Table 2 reports the poverty and vulnerability statistics by trading sector. For each surveyed year, in the first two columns it shows the characteristics of households in terms of income distribution (proxied by the percentage of population below the fourth decile of the income distribution) and poverty rates (percentage of population below the poverty line). In the last two columns for each surveyed year, it shows as in Table 1 the total percentage of vulnerable households and the percentage of vulnerable households that are considered as risk induced. As can be seen in the Table 2, under the period of observation, the percentage of vulnerable people decreased in all trade-related sectors following a quite regular pattern (with some jumps moving from VLSS to VHLSS, probably due to the substantial

$V_{h,t+k} = 1 - [P(\ln c_{ht} > \ln z)]^k$, given the information set at t . In this exercise we use $k = 2$.

¹⁸Imai et al., (2011) suggest a method of making such a comparison by means of a multinomial logit model, adding $VEP_{h,t-1}$ as one of the arguments.

3.4 The empirical analysis

difference in the sampling frame between the two surveys). As a result, in 2008 (our last year of observation), all trade-related sectors register, without exception, a lower percentage of vulnerable households than in 1992. Nevertheless, farm activities show higher percentages than non-farm ones with the relevant exception of non-traded crops.

According to our VEP estimates, the sectors with the lowest percentage of vulnerable households are non-traded services (they also show the lowest percentage of poor people and, in general, of people with income below the fourth decile¹⁹) and non-traded crops (in both cases, the percentage of vulnerable households is below 2% in 2008). Among farm activities, the production sector with the highest percentage of vulnerable households is import-competing sectors followed by rice. Acknowledging the peculiar nature of the rice sector which is, at the same time, the main production sector and the main source of food for Vietnamese households, the last two rows of Table 2 also show the decomposition of vulnerability patterns between rice net producers and net consumer households where both the percentages of the poor and vulnerable are higher among net rice producers than among net rice consumers. Notwithstanding the fact that households involved in main-export crops share similar mean income/consumption levels with those involved in non-traded services (see Table A.2), the percentage of vulnerable people in the former is permanently higher than in the latter. This is noteworthy if we consider the relatively low incidence of poor households in export crops and the relative equal distribution of income across deciles that characterise it (see the first two columns in Table 2). Hence, we can argue, first of all, that the hypothesis of heterogeneity in vulnerability by trade sector is not rejected by the empirical data in Vietnam. Furthermore, it should be noted that all non-farm activities register in 2008, generally speaking, a higher share of risk-induced vulnerability than farm ones where import-competing crops and rice seem to be the least exposed. Although this share is computed on a smaller total, this is a relevant issue for policymaking. However, it is intrinsically related to one of the main VEP weaknesses (i.e., the inability to model risk explicitly)²⁰. To this end, the next section tries to overcome the VEP approach, specifically, by shedding light on the black box of the risk-induced VEP component and disentangling the relative “importance” of its various determinants.

¹⁹Note that, except in 1992, there are no poor households in the fifth or higher decile of income.

²⁰It is worth recalling here that the VEP measure assumes that the observed inter-household distribution of consumption at a point in time represents the future distribution of consumption across states of the nature for each household.

Table 2: Vulnerability to expected poverty by trade-related sectors

Trade sectors	1992						1998						2002

3.4 The empirical analysis

The net contribution of “risk-induced” determinants of vulnerability

Table 3 reports the estimated coefficients of our consumption regression (eq. 8) for each round of the observations. In these estimates, the current value in thousand dong of the households’ fixed assets and durable goods has been used as a proxy for wealth in the denominator of the scaling factor. The estimated coefficients of the same equation using the linear combination of the principal component factors of a sub-set of housing characteristics and physical land availability as a proxy for wealth in the denominator of the scaling factor are reported in Table 3C-4 in Appendix 3C. For an idea of how these alternative strategies actually soften possible endogeneity bias in the relationship between current consumption and expected wealth, Table 3C-5 in Appendix 3C reports the coefficients of the same estimates using observed consumption as a measure of wealth in the scaling factor.

As shown in Table 3, all the covariates are statistically significant and show the expected signs. The signs of age and its square coefficients confirm, in principle, the well-known concave age-consumption profile, even if the decreasing rate is in this case meaningless. Not surprisingly, having children reduces household per capita consumption while being married increases it. Whether the head of the household is male or female is correlated with consumption too. The education variables also behave as expected, that is, higher levels of education actually correspond to higher levels of consumption. Lastly, the presence of a set of village characteristics (urban status and availability of paved roads, electricity, tap water and public transport) are associated with a higher level of consumption too.

The striking feature of our empirical exercise lies in the fact that both our *ex-post* and *ex-ante* stochastic components of income are significantly correlated with household consumption behaviour.²¹ More specifically, in each of the surveys under analysis there is a negative correlation between the *ex-ante* component of income innovation and expected consumption (although this is not statistically significant for some of the available rounds). The same relation holds for the *ex-post* negative shocks.

Even if our exercise cannot be considered a proper test of the precautionary saving theory - because of its static nature - our results are consistent with the provisions made by the theory, that is, *ex-ante* risk implies a lower level of current consumption. In other words, our consumption estimates confirm that households are, generally speaking, lowering their current path of consumption because of both *ex-ante* risk (as a function of mitigating strategies) and *ex-post* negative shocks (as a function of coping strategies)

²¹The outcomes of the income equation (eq. 4) which are used to separate the *ex-ante* and *ex-post* components of risk, are reported in Table 3A-5 in Appendix 3A.

with negative welfare implications in their consumption prospects. It also highlights the presence of *ex-ante* welfare effects (i.e., changing behaviour in consumption because of “ex-ante” risk) for households that did not actually experience any shock. Note that this is based on a better identification strategy able to separate *ex-ante* and *ex-post* risks. However, as will be discussed below, we cannot rule out measurement errors and unobservable bias because of the lack of panel data.

Table 4 shows the standardised coefficients in Eq. 8.²² As can be seen in Fig. 1, which plots the standardised coefficients in Eq.8, the ex-ante stochastic component (i.e., the income risk variable) does not matter as much as the other components.²³ However, if we look at the evolution of its net contribution over time²⁴ for the entire period under observation (1992-2008), we see that the risk component influences consumption negatively in every round of observations and does not evidence a clear downward trend (with the significant exception of a strong reduction from 1992 to 1998 within the VLSS, see Fig. 2)

Table 3C-1 in Appendix 3C reports additional estimates for eq. 8 which also include dummies for trade categories. On the one hand, this helps us capture possible unobservable income effects other than those already controlled for by the observable characteristics, neutralising differences in average income between groups (i.e., households in different trade categories show heterogeneous consumption because of heterogeneous income). On the other hand, while the risk term is supposed to capture in principle both within and between group effects, the inclusion of trade categories acknowledges that some risks can be common to households in the same trade group and allows us to isolate the risk effect within groups (i.e., risks are identified within the groups) better than in the estimates reported in Table 3.²⁵ The outcomes reported in Table 3C-1 show the following stylised facts: i) the trade dummies show, generally speaking, negative coefficients, i.e., they are associated with lower consumption prospects than the reference category (non-farm non-trade); ii) the overall fit of the model with the trade dummies slightly improves; iii) the coefficients of the risk terms do not change signifi-

²²Standardised coefficients are simply the regression coefficients when all variables have been standardised to mean zero and variance one (z scores). For more details, see Achen (1982).

²³These outcomes are very much in line with the other Essays in this thesis and with Lucas (2003)’s computations.

²⁴The net contribution on consumption behaviour is here intended simply as its “level importance”, computed by multiplying the mean of the independent variable by its coefficient.

²⁵It is useful here to remark that equality of the means and variances of income residuals by trade categories is rejected by the data.

cantly. The above evidence suggests that the trade dummies mainly capture differences in mean income which do not influence the risk channel depicted above.

As a further robustness check, Table 3C-4 in Appendix 3C reports additional estimates of eq. 8 with a linear combination of housing and land availability as principal component factors to proxy for wealth in the denominator of the π term. It also includes the trade dummies in the regression. It is worth noting that in the case of the VLSS rounds, the use of this index dramatically reduces the number of observations because of the high number of missing observations. It actually hampers the degree of confidence of the regression outcomes for these rounds. In the case of the VHLSS rounds, however, the negative relationship between income risk and consumption is still there even if only weakly significant for some rounds. Finally, the same estimates are reported in Table 3C-5 using observed consumption as a proxy for the expected wealth of the denominator of the scaling factor. They show the same pattern. The only difference, as expected, is that the coefficients for ex-ante risk are higher in magnitude and more significant in all rounds. In short, the negative relationship between ex-ante risk and consumption seems to hold and is robust to alternative empirical proxies for wealth.

Before drawing any conclusion, however, we should mention that the lack of panel data prevents us from isolating the risk component properly. If we correctly assume the variance of income innovation as a comprehensive mea-

sure of risk component, variance in non-stochastic household heterogeneity and variance in measurement error, it is apparent that our estimates should be seen as an upper-bound of the possible welfare impact of the risk component. However, is the hypothesis of time-varying heterogeneity and measurement error reasonable?

On the one hand, while the VHLSS data are universally considered to be of better quality than VLSS and widely used by both national and international research communities, as already discussed, we cannot exclude the presence of time-varying measurement error in income (Lee et al., 2010; Glewwe, 2011).²⁶ Furthermore, in a dynamic emerging economy like Vietnam, in the midst of a deep and comprehensive process of reform such as *Doi Moi*, we cannot exclude the presence of time-varying unobserved household heterogeneity either.

On the other hand, if we come back to the main focus of our analysis, i.e., the trade openness debate, and we test whether or not there are likely to be statistical differences in the *ex-ante* component of income innovation across households in relation to their affiliation to each trade-related group, the F-statistics of the one-way ANOVA and the Levene's T-test²⁷ reject in each round of observations the null hypotheses that the means and the variances of the estimated income residuals are the same across trade-related production groups (Table 5). We are thus confronting heterogeneity in unexplained stochastic components when households are gathered by trade-related sectors (see Figure 3 for the full picture of the dispersion of income residuals across households by trade-related category for all the available households surveys).

Fig. 4 shows, as in Fig.2, the evolution of the net contribution of the *ex-ante* component of income innovation on households' consumption behaviour (derived from estimating Eq. 8), by clustering households across groups of industries classified as traded, not traded and rice, according to Coello et al. (2010). The picture highlights a relatively higher average of the *ex-ante* stochastic component in the case of the trading sectors compared with the other ones, especially in the most recent rounds, net of the usual jump between VLSS and VHLSS.

This last result confirms that we are confronting heterogeneity in the variance of income innovation which is correlated to the relative degrees of trade openness of production sectors. Again, if we are willing to assume

²⁶For instance, being selected for the VHLSS survey has been seen to have an independent increasing positive impact on average household consumption (Hansen and Trung Dange, 2010).

²⁷The Levine test is similar to the standard one-way Anova test, but less sensitive to the eventual violation of normality assumption. The null hypothesis of both tests is equality of variances across trade groups. This is rejected with a probability of below 0.05.

3.4 The empirical analysis

3.4 The empirical analysis

Figure 4: Evolution of the net contribution of the risk component on average household consumption (1992-1008) in traded, not traded and rice sectors

it is the upper bound of a proper measure of the risk component, the plain conclusion is that, not only is risk increasing over time in Vietnam under *Doi Moi*, but that its relevance (in terms of net contribution both to the expected average and to the variance of household consumption) is proportionally higher the higher the trade exposure of the sector the household is involved in.

However, since we acknowledge that we are not able to separate pure risk from unobserved household heterogeneity and measurement error, we cannot make this conclusion without considering the opposite hypothesis. To this end, let us suppose that our *ex-ante* component is entirely determined by unobserved household heterogeneity and measurement error. This means that both the unobservable heterogeneity and measurement error change according to household trade exposure across sectors, i.e households working in a more exposed trading sector are more, and increasingly, severely affected by unobservables and measurement error than households working in a less trade-exposed sector. This would indeed be an interesting conjecture, even if it has not been explored by the literature so far. But even so, why should their impact on consumption behaviour be negative? Such a hypothesis would need to assume that the households that self-select to participate in the more exposed trade sectors present a set of common characteristics,

unobserved to the researcher, or alternatively, a common path in their relative measurement error, that have a negative impact on their consumption behaviour. If that were the case, it would be a very relevant issue for policymaking and would also imply a revision of the assumed trade benefits for the welfare of Vietnamese households working in the most exposed trading sector, at least partially, i.e., when looking at heterogeneity in their unexplained stochastic components of consumption behaviour. My impression, however, is that we are probably simply assessing what we are looking for: i.e., the dynamic of risk heterogeneity across households according to their degree of risk exposure. This is reasonably increasing over time and is relatively higher for the households that are more exposed to trade due to the relative impact of foreign risks. Furthermore, it is negatively correlated with *ex-ante* consumption behaviour even for the households that do not actually experience any shock.

3.5 Conclusions

This paper presents - to the best of my knowledge - the first comprehensive analysis of vulnerability to poverty induced by trade liberalisation in Vietnam under *Doi Moi* for the entire period 1992-2008. As a result, a number of useful insights into the phenomena under analysis can be derived. First of all, a decreasing trend in vulnerability to poverty along with a decreasing trend in poverty; second, a non-decreasing share of risk-induced vulnerability and; third, the non-decreasing importance (both in terms of impact level and in terms of dispersion) of the vulnerability component of consumption behaviour linked to the *ex-ante* stochastic determinants, an issue traditionally overlooked by the empirical literature in the field. Finally, our estimates confirm that risk exposure varies systematically according to the trade exposure of surveyed households. Notwithstanding the fact that households involved in main-export farm activities share similar mean income/consumption levels with those involved in non-traded non-farm ones, the percentage of vulnerable people in the former is permanently higher than in the latter. While the nature of the heterogeneity of the *ex-ante* income innovation by trade-related sector as well as the role of risk management strategies actually engaged in by Vietnamese households need more careful investigation, these first empirical outcomes appear to be very relevant to policymaking. They highlight the need to include possible influences of trade-related risk exposure in the welfare assessments of the impacts of trade policies.

Appendix 3A - Tables & Figures

Table 3A-1: Industries classification by trade-related sectors

Exports Non-Farm	Non-traded Non-Farm
Fishing, aquaculture Mining of coal and lignite; extraction of peat Extraction of crude petroleum and natural gas Wearing apparel; dressing and dyeing of fur Footwear Wood and of products of wood and cork Office, accounting and computing machinery	Recycling Electricity, gas, steam and hot water supply Collection, purification and distribution of water Construction Sale, maintenance and repair of motor vehicles Wholesale trade and commission trade Retail trade, repair Hotels and restaurants Land transport; transport via pipelines Water transport Air transport Supporting and auxiliary transport activities Post and telecommunications Financial intermediation Insurance and pension funding Activities auxiliary to financial intermediation Real estate activities Renting of machinery and equipment Computer and related activities Research and development Other business activities Public administration and defence Education Health and social work Sewage and refuse disposal, sanitation Activities of membership organizations n.e.c. Table 3A-2: List of fixed assets and durable goods used to proxy households' wealth

Perennial crop gardens	Telephone sets
Aquaculture production area	Mobilephones
Fish/shrimp-rearing cages/rafts	Sewing, weaving, embroidering machines
Other production land area	Other machines and equipment
Buffalo, cow, horse for production and breeding	Fishing net
Breeding male and female pig	Durable containers for storage
Basic herds of poultry and cattle	Other professional equipment
Breeding facilities	Video players
Feed grinding machines	Color T.V sets
Rice milling machines	Black and white T.V sets
Rice plucking off machine	Multi-tier stereos
Pesticide sprayers	Radios/Cassette
Workshops	Recorders/Disc players
Shops	Computers
Other production bases	Cameras, Video cameras
Cars	Refreezerators, Freezers
Tractors	Air-conditioners
Trailers	Washing machines and driers
Tractor ploughs	Electric fans
Motorbikes	Water heaters
Bicycles	Gas cookers
Cart	Electric cookers, rice cookers, pressure cookers
Motor boats, ferries ...	Trollers of various kinds
Boats, ferries without motor	Wardrobes of various kinds
Other means of transportation	Beds
Lathes and welding and milling machines	Tables, chairs, sofas ...
Punchers	Vacuum cleaners, water filters
Wooden sawing machines	Microwaves
Pumps	Liquidizer, juicer
Power generators	Other valuable things
Printers, photocopiers	(Antiques, pianos, dressing tables...)
Fax machines

Appendix 3B - The VEP estimation procedure

VEP method uses an ordinary least squares (OLS) procedure to estimate a standard reduced-form of the consumption function based on the following simple linear econometric specification:²⁸

$$c_{ht} = \alpha + \beta X_{ht} + \varphi V_t + \epsilon_{ht} \quad (3B-1)$$

where c_{ht} is the log of per capita consumption of household h at time t ; X and V are two vectors of exogenous variables which control, respectively, for the households and villages characteristics; ϵ_{ht} is an error term. It acknowledges the stochastic nature of consumption simply by noting that the error term in Eq. 3B-1 is not the same for all households (i.e., violation of the homoskedasticity hypothesis), rather there is heterogeneity in consumption volatility around the mean. Thus, it addresses the issue, by using a 3-steps Feasible Generalized Least Squares (FGLS) econometric procedure suggested by Amemiya (1977). At first, it estimates the residuals from the equation 3B-1 and run the following estimating process of the error variance assumed as a function of the same covariates included in the specification of the consumption process. Specifically, we have:

$$\epsilon_{ht}^2 = \delta X_{ht} + \lambda V_{ht} + \eta_{ht} \quad (3B-2)$$

Eq. 3B-2 solves the heteroskedasticity problem and contributes to build up efficient estimates of the expected consumption level. From an economic perspective, it provides a robust method to link the households characteristics to the amount of unexplained consumption which is peculiar to vulnerability analysis. The outcomes of the regressions of Eq. 3B-2 are reported in Table 3B-1.

The predictions of Eq. 3B-2 are thus used to weight the previous equation, obtaining the following transformed version:

$$\frac{\epsilon_{ht}^2}{\epsilon_{ht,OLS}^2} = \delta \frac{X_{ht}}{\epsilon_{ht,OLS}^2} + \lambda \frac{V_{ht}}{\epsilon_{ht,OLS}^2} + \frac{\eta_{ht}}{\epsilon_{ht,OLS}^2} \quad (3B-3)$$

As reported in Chaudhuri (2003), the OLS estimation of Eq. 3B-3 gives us back an asymptotically efficient FGLS estimate, δ^{FGLS} , λ^{FGLS} and thus ϵ^2 is a consistent estimate of σ_{ht}^2 , the variance of the idiosyncratic component of

²⁸It is worth noting that such a simple specification of the consumption function has already been used by previous works on poverty in Vietnam which exploit the same VLSS and VHLSS surveys, e.g. Glewwe et al. 2002; Minot and Baulch 2005; Niimi et al. 2007; Justino et al. 2008; Cuong et al. 2010, Nguyen and Winters 2011.

household consumption. Once we obtain an efficient estimate of the variance we can finally take the square root of it and transform Eq.3B-1 as follows:

$$\frac{\ln c_{ht}}{\widehat{\sigma}_{ht,FGLS}} = \theta \frac{X_{ht}}{\widehat{\sigma}_{ht,FGLS}} + \phi \frac{V_{ht}}{\widehat{\sigma}_{ht,FGLS}} + \frac{\eta_{ht}}{\widehat{\sigma}_{ht,FGLS}} \quad (3B-4)$$

The OLS estimation of Eq. 3B-4 provides consistent and asymptotically efficient estimate of θ^{FGLS} ; ϕ^{FGLS} . It is thus possible to estimate both the expected log consumption and its variance as follows:²⁹

$$\widehat{E}[\ln c_{ht}|X_{ht}, V_{ht}] = \theta^{FGLS} X_{ht} + \phi^{FGLS} V_{ht} \quad (3B-5)$$

$$\widehat{Var}[\ln c_{ht}|X_{ht}, Y_{ht}] = \delta^{FGLS} X_{ht} + {}^{FGLS} V_{ht} \quad (3B-6)$$

To compute the vulnerability rates in Table 1 households are considered vulnerable to expected poverty if they show a probability of being poor (\widehat{V}_h) bigger than that of being non-poor ($1 - \widehat{V}_h$), which seems to us a fair decision strategy. To better clarify the concept, it is useful to provide a representation of the distribution of the aggregate VEP vulnerability across different thresholds and comparing it across the different years of observation. Figure 3B-1 shows the relationship between the incidence of vulnerability in the total population (on the vertical axis) and the different probability thresholds (on the horizontal axis, ranging from 0 to 1). To understand this relationship it is useful starting from the extreme cases: when the probability threshold is set to zero, all the households should be considered as vulnerable (no households in Vietnam show a probability equal zero to fall below the poverty line); when the probability threshold is set to one, the vulnerability incidence on the total population is equal to zero (no households show full probability to fall below the poverty line). Consequently, it is straightforward to see that when the probability threshold is set somewhere in between, the percentage of vulnerable households over the total population falls somewhere in between too.

Table 1 in section 3.4 reports the vulnerability rates as percentage of total population (vertical axis) corresponding to 0.50 on the horizontal axis. For instance, comparing the picture of 1992 with 1998 it is straightforward to see the jump in the VEP figures reported in Table 1 (the upper line corresponding to 0.50 probability threshold is above the 50% of total population on the vertical axes in 1992 it is in fact 56.11% - and largely below 50% in 1998

²⁹To address measurement errors and likely omitted variable bias, Chaudhuri and Datt (2001) make a multiplicative adjustment to the estimated variances such that the predicted mean of the consumption be equal to its observed mean for each year of estimation.

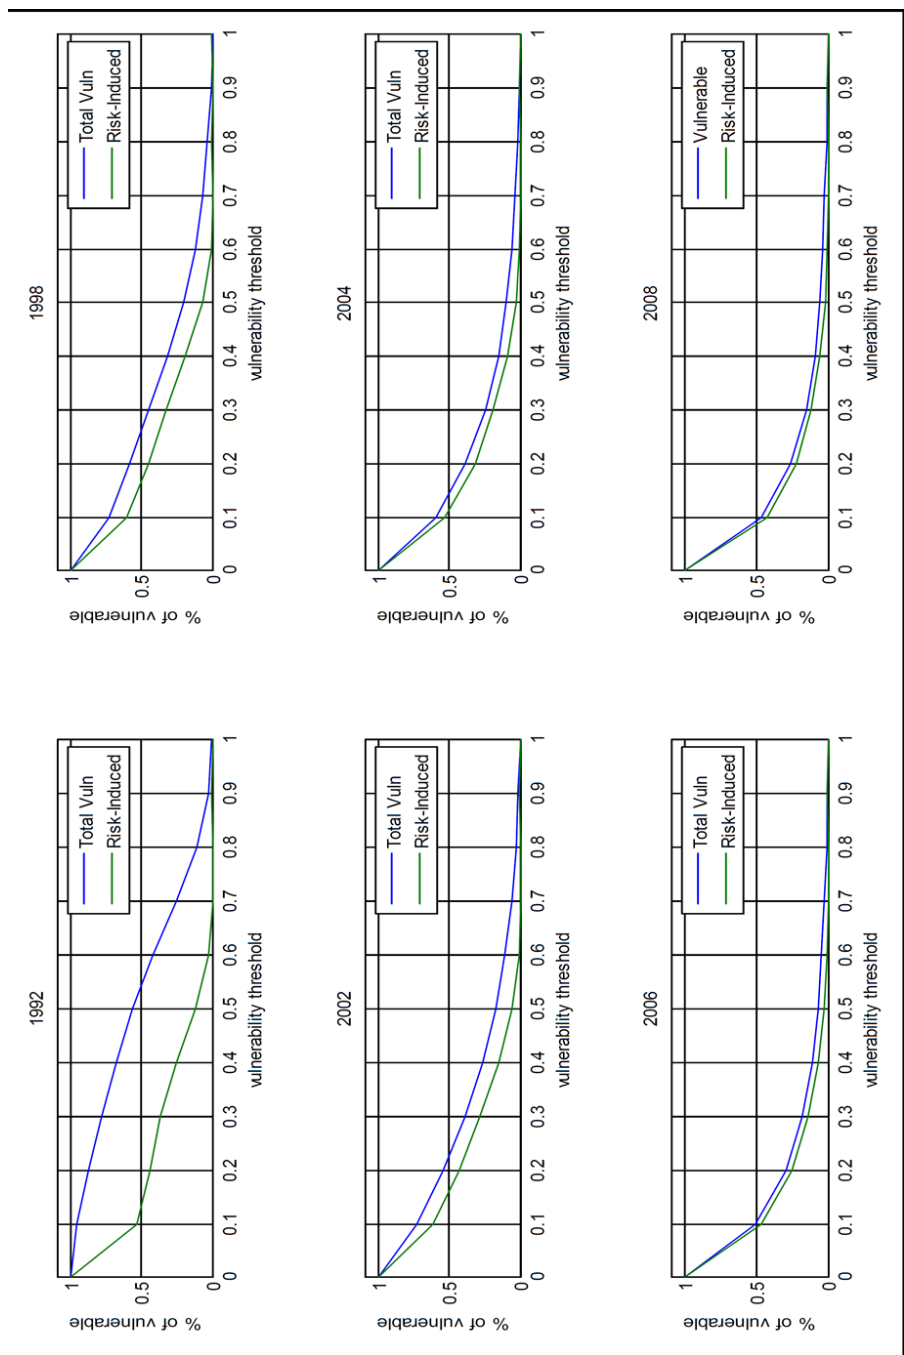

it is actually 21.50%). Thanks to Figure 3B-1 we can see that a similar pattern is actually in place for different probability thresholds and that the decreasing trend of vulnerability is apparent for all the possible thresholds. This is evident looking at the decreasing slopes of the curves representing vulnerability which become increasingly convex year after year. From this figure it is also easy to detect the narrowing gap between the fraction of risk induced vulnerable within the overall vulnerable population. As we can see from the Figure 3B-1, the distance between the two lines decrease over time, indicating that recently most of the Vietnamese households are vulnerable not because of their structural characteristics, rather because of the presence of risk.

Chapter 4

Essay 4 - Trade openness and vulnerability to poverty in Vietnam: a panel empirical test in the period 2002-2006

This paper assesses trade-induced vulnerability in Vietnam by presenting an extended version of Ligon and Schechter's (2003) measure of Vulnerability as low Expected Utility (VEU) and using the VHLSS panel data available for 2002-06. The empirical results show that risk-induced vulnerability and heterogeneity in trade exposure by industry matters in determining household overall vulnerability. They also show that the *ex-ante* permanent risk is significantly correlated with both the non-stochastic, via the precautionary saving channel, and the risk components of vulnerability and that this correlation actually increases for the upper percentiles of vulnerability distribution (with the most vulnerable households being the most severely affected). This work is relevant to policymaking since it is, to the best of my knowledge, the first empirical evidence of the direct influence of the trade-related risks on household vulnerability in a panel setting.

Keywords: trade openness, vulnerability, poverty, risk, consumption behaviour, Vietnam.

JEL: F14, O12, D12, C31

4.1 Introduction

Various attempts have been made to empirically investigate the link between trade liberalisation and household welfare in Vietnam under *Doi Moi*, focusing mainly on the impact of liberalisation on poverty indicators (Justino et al., 2008; Jenkins, 2004; Nadvi et al., 2004; van de Walle and Cratty, 2004; Jensen and Tarp, 2005; Nguyen and Ezaki, 2005; Fujii and Roland-Holst, 2007; Niimi et al., 2007; Abbott et al., 2009; Heo and Doanh, 2009; Coello et al., 2010). Few attempts have been made to date to further investigate the impact of the Vietnamese opening process on *ex-ante* measures of vulnerability to poverty and the consequent role played by the permanent components of risk associated with trade liberalisation. This can be considered a remarkably weakness since trade can alter a household's risk exposure and its vulnerability. As shown in Essay 2, risk-averse people react to risk by modifying their optimal behaviour, thus encouraging additional/extra saving and reducing current consumption. Although consumption fluctuations are seen as optimal responses to risk, they imply a smoothless path of consumption which in turn implies permanent negative effects on welfare. This is especially true for people characterised by a poor ability to take advantage of the positive opportunities linked to trade reforms and weak mitigating strategies. In the midst of trade reform they carry out extra-saving and follow conservative choices shying away from profitable but risky investments (Winters et al., 2004).

To deal with this issue, here we propose a novel empirical approach to isolating the trade-induced component of vulnerability, taking into account the different role played by the *ex-ante* effects of risk and the *ex-post* effects of shocks. More specifically, we present: i) an extended version of the Ligon and Schechter's (2003) measure of Vulnerability as low Expected Utility (VEU) able to isolate the component of risk-exposure associated with trade openness (i.e., risks that are not fully shared across trade-related industries) as well as the *ex-ante* effects of risk from the *ex-post* effects of shocks; and ii) an empirical application of the proposed extended measure by exploiting the panel data available in Vietnam for the period 2002-06.¹

Our results show that i) trade exposure and its related risks matter in determining household overall vulnerability; ii) the *ex-ante* permanent risk is significantly correlated with both the "random" and "non-random" components of vulnerability; iii) the relative impact of the *ex-ante* permanent

¹The VHLSS collected information from a sample of 29,530 households in 2002 of which 4,476 were re-interviewed in 2004 and 2006, out of samples of 9,188 in total in 2004 and 9,189 in 2006. A new wave was also collected in 2008 but, unfortunately, it does not include panel data with the previous rounds.

4.2 Trade and vulnerability to poverty: the conceptual framework

risk actually increases for the upper percentiles of vulnerability distribution (with the most vulnerable households being the most severely affected).

This empirical evidence has strong policy implications. Although it does not represent, by any means, an argument against free trade, it is a quest to deepen our knowledge on the stabilisation needs of trade reforms, e. g., the promotion of credible stabilisation policies (e.g., reducing price fluctuations) and/or the design of new insurance schemes that target vulnerable households (e.g., raise the creditworthiness of small farmers' participation in export cropping).

The paper is organised as follows: Section II reviews the literature and presents the conceptual framework on trade and vulnerability to poverty; Section III provides the details on the adopted vulnerability measure; Section IV presents the empirical model and the data; Section V the empirical results and Section VI concludes.

4.2 Trade and vulnerability to poverty: the conceptual framework

Trade theory is mainly focused on the first moment of the relationship between trade openness and welfare which is incomplete when people are risk averse. Empirical evidence is mixed, scattered in separate fields of analysis and does not reach a common stance. As a result, current literature fails to make a full assessment of the net welfare impact of the opening-up process (see Essay 1).

In principle, trade openness could alter households' optimal portfolios, so that their current ones become sub-optimal *ex-ante*.² This is because trade openness can alter risk, impact on households' optimal portfolios, and lead to net welfare effects that are less positive than expected in the long run (Winters, 2002; Winters and al., 2004; Calvo and Dercon, 2007a).

As a result, households in the midst of trade reforms may decide to employ strategies to mitigate risks and reduce welfare variability.³ These actions can

²Of course, *ex-post*, a household may lose out because of unlucky realisations. Hence, increases in observed poverty can be consistent with *ex-ante* improvements in welfare if households trade higher mean incomes for higher variances (Winters et al., 2004).

³Both management and coping strategies can operate through i) an informal channel, which includes personal, family and community arrangements; ii) a market-based channel, based on the opportunity provided by institutions such as banks, insurance or microfinance corporations; or iii) a public channel, which implies a series of welfare state interventions aimed at protecting specific subsets of the population, e.g. measures to deal with unemployment, old-age, work injury, disability, widowhood and sickness.

4.2 Trade and vulnerability to poverty: the conceptual framework

imply conservative choices, especially for the poor, that lower the expected value of income (and consumption) in exchange for lower variability.⁴ While consumption fluctuations are seen as optimal responses to risk, they imply a smoothless path of consumption. Hence, these strategies can be costly in the short run because they encourage additional/extra saving and reduce current consumption (Kimball, 1990; Caballero, 1990; Deaton, 1992; Carroll, 2001; Carroll & Kimball, 2008) with permanent negative effects on welfare (Ravallion 1988; Morduch 1994; Dercon, 2005).

Consequently, any measure of vulnerability which is not able to adequately take into account trade exposure and the effect of the *ex-ante* change in behaviour induced by trade liberalisation is lacking an important component of welfare analysis.

To undertake the issue operationally, here we propose a workable measure of vulnerability that is able to isolate the net welfare cost of trade exposure and the relative effect of the *ex-ante* changing behaviour under trade risks. We then apply this measure to the VHLSS panel data for the available period 2002-06 to test the presence of heterogeneity in households' vulnerability associated with their degree of trade exposure. More specifically, our hypothesis is that the presence of heterogeneity in vulnerability scores is associated with heterogeneity in risk exposure and/or in the adopted mitigating strategies between households involved in "traded" and "non-traded" sectors. This is because while households engaged in non-traded sectors are mainly affected by domestic risks (e.g., bad weather, crops failure, livestock diseases, etc.), households engaged in import- and export-related sectors are also affected by foreign markets' risks (e. g, international price fluctuations, exchange rate fluctuations, etc.). This heterogeneity in risk exposure leads, *ceteris paribus*, to heterogeneity in risk management strategies including changes in their *ex-ante* consumption behaviour.

Note that the focus here is on behavioural heterogeneity. We do not make any additional assumption regarding the typology and sign of possible correlations between domestic and foreign risks (an issue on which empirical evidence has been somewhat inconclusive, see McCulloch et al., 2001) since this it is neither necessary nor particularly informative for our empirical analysis. Furthermore, we acknowledge that the presence of significant differences in vulnerability across households employed in different trade-related sectors

⁴The literature on income smoothing mainly focuses its interest on aspects related to farm production such as the intensity of input adoption (Morduch, 1990; Dercon and Christiaensen, 2011), diversification of activities (Morduch, 1990, Townsend, 1995, Dercon, 1996), occupational choices (Rosenzweig and Stark, 1989; Kochar, 1999; Rose, 1995) and their net impact on the expected profit of the household (Rosenzweig and Binswanger, 1993).

of specialisation does not provide information on the nature of the foreign risks and/or their channels of transmission to changes in household welfare. However, it is undeniable that the presence of heterogeneity in vulnerability scores across households classified by trade exposure strongly suggests the need for further, more detailed, analyses of the links between trade and vulnerability which is an issue that has so far been ignored in the specialised literature, both theoretical and applied.

4.3 Vulnerability as Expected Utility for trade analysis

In order to isolate the trade risk component of vulnerability, in this Essay we propose an extended version of Ligon and Schechter's (2003) measure of Vulnerability as low Expected Utility (VEU). By using a utilitarian approach, VEU assesses vulnerability as the difference between the utility derived from some level of certainty-equivalent consumption (based on and analogous to the choice of a poverty line in the literature of poverty measurement, z) above which the household would not be considered vulnerable, and the expected utility of consumption $[EU_i(c_i)]$, as follows:

$$V_i = U_i(z) - EU_i(c_i) \quad (1)$$

where U_i is a weakly concave, strictly increasing function.⁵ Taking expectations of the increasing, concave function of consumption expenditures has the effect of making vulnerability depend not only on mean consumption, but also on its variation over time (Ligon and Schechter, 2003). To this end, VEU disentangles "poverty-induced" vulnerability - as a low expected mean of consumption - from "risk-induced" vulnerability, linked to consumption fluctuations, as follows:

$$V_i = [U_i(z) - U_i(E(c_{it}))] + [U_i(E(c_{it})) - EU_i(c_{it})] \quad (2)$$

where $E(c_{it})$ indicates the non-random expected level of consumption (i.e., the certainty equivalent consumption). While the first bracketed term of Eq.2 involves no random variables, the second one measures the "risk premium", i.e., the amount of utility the household would be prepared to give up rather than face a risky prospect. This is the "natural" counterpart,

⁵This method applies to the class of von Neumann-Morgenstern expected utility functions.

4.3 Vulnerability as Expected Utility for trade analysis

denominated in utils, of the risk premium the household would be willing to forego in order to eliminate risk.⁶

The VEU method overcomes the weak theoretical background of the most popular vulnerability measures based on expected values of the common Foster-Greer-Thorbecke (FGT) class of decomposable poverty measures.⁷ Furthermore, it is micro founded, empirically based, and presents some clear advantages over other groups of micro-founded vulnerability measures, e.g., the class of vulnerability measures looking at the threat of poverty (VTP) (Calvo and Dercon, 2013; Povel, 2015, Chaudhuri et al., 2002; Kamanou & Morduch, 2004; Pritchett, Suryahadi, & Sumarto, 2000; Dutta et al., 2011; Gunther & Maier, 2008).⁸ First, unlike the VTP class of measures, VEU addresses vulnerability to risk only after aggregation across states has been performed (Calvo, 2008). It implicitly assumes that it measures vulnerability net of the adoption of all the feasible precautionary saving and/or other insurance mechanisms whereby households can smooth away, even if not fully, variations in outcomes over states of the world. Second, VEU empirical applications overcome the need to approximate all possible states of the world, a somewhat heroic assumption of the VTP class of measures using the short panel data currently available in developing countries.

Notwithstanding its virtues, the VEU measure presents drawbacks too. First, it treats mean consumption as being independent of risk, implying that risks affect only the volatility of consumption around its mean, but not the mean itself, thus underestimating the overall effect of risk (Elbers and Gunning, 2003). Second, it does not distinguish between whether vulnerability is generated by exposure to shocks, i.e., the lack of coping mechanisms (*ex-post* effects), or risk-induced change in behaviour, i.e., the long-term cost of undertaking *ex-ante* mitigating strategies (*ex-ante* effects). The latter issue is prominent since, as underlined in the previous sections, this distinction should be considered as an unavoidable element in the design of policy interventions.

To overcome the above caveats, we provide an extended version of the VEU measure for trade and vulnerability analysis in three steps.

⁶The concavity of the utility function implies that the so-called “Jensen’s inequality” holds, i.e., the difference between the utility of consuming the expected consumption with certainty and the expected utility from consuming c_i is positive, on average.

⁷For a survey of the main methods applied in vulnerability analysis, please refer to the Appendix 1.A in Essay 1.

⁸VTP measures compute vulnerability as the *ex-ante* probability weighted average[s] of state-specific indices of deprivation. The main advantage of this group of measures is that vulnerability is associated with the extent that poverty cannot be safely ruled out in any of the possible future scenarios (Calvo, 2008).

4.3 Vulnerability as Expected Utility for trade analysis

First, following on from Ligon and Schecher (2003) and Ligon (2006), we further decompose the risk component of the VEU measure filtering out “aggregate risk”, “meso (trade-related) risk” and “measurement error and idiosyncratic risk” respectively, as follows:

$$\begin{aligned}
 V_i = & [U_i(z) - U_i(Ec_{it})] + & (\text{Poverty}) \\
 & [U_i(Ec_{it}) - EU_i(E(C_{it}|\mu_k))] + & (\text{trade-related risk}) \\
 & [EU_i(E(C_{it}|\mu_k)) - EU_i(E(C_{it}|\mu_k, \mu_t))] + & (\text{Aggregate risk}) \\
 & [EU_i(E(C_{it}|\mu_k, \mu_t)) - EU_i(c_{it})] + & (\text{Measurement error and idiosyncratic risk})
 \end{aligned}
 \tag{3}$$

where μ_t is an aggregate risk term, common to all households, which may vary over dates and (aggregate) states; μ_k represents a risk term which varies across k clusters of households that are supposed to be characterised by heterogeneity in their exposure to foreign risks.⁹ The rationale of this further decomposition is the following: with complete markets, household i ’s consumption is supposed to vary over time only in response to aggregate shocks (i.e., common to all households). However, if we assume heterogeneity in risk exposure between households involved in traded and non-traded sectors, we should verify that risks are not fully shared across them (because they are different in nature and/or because the lack of appropriate risk-sharing mechanisms) and that aggregate risks do not affect households homogeneously. To take this into account in our vulnerability measure, we filter out a further “meso component” able to capture any systematic variation in the expected level of log consumption across households classified by trade clusters. A simple joint significance test of the latent terms will provide an appropriate empirical test for this intuition (see section IV). To this end, it seems more natural to look at the aggregate/covariate risk as a residual sub-component of the VEU overall risk component after controlling for trade groups’ deviations from risk sharing. If, on the other hand, we filter out the trade groups’ deviations from the overall component of aggregate risk, this will imply that deviations from risk sharing by trade categories are considered as the residual subcomponent of the VEU overall risk component. Since trade cannot be considered orthogonal to time risks (i.e., they are correlated), both strategies are legitimate. Of course, the first component always captures all the common elements and, for this reason, we adopt the first strategy as the preferred one: it gives more emphasis to the trade-related risk component (Figs.1 and 2 show the comparison of the decomposition of overall risk using

⁹A similar procedure has been followed by Ligon (2006) for a different purpose.

4.3 Vulnerability as Expected Utility for trade analysis

the two different strategies highlighting this difference). It is worth noting that in all cases, we are simply attempting to provide alternative possible distributions of the VEU overall risk component - which remains invariant - into trade-related and non-trade-related sources. The added value is to exclude possible extreme interpretations that Vietnamese households are facing alternatively only trade-related risks or only non-trade-related risks.¹⁰ The final sub-component in Eq. 3 contains the remaining idiosyncratic risk, i.e., any systematic deviation by households from the predictions of complete markets, other than trade risk heterogeneity, and likely measurement errors.

Second, as suggested by several authors (Elbers and Gunning 2003, Elbers et al. 2007, Elbers et al. 2009, Carter and Ikegami, 2009), we assume that households correctly perceive the distribution of risk they face even when they do not actually experience any shock. Hence, we further decompose the final sub-component of Eq. 3 by filtering out two additional sub-components of vulnerability: the *ex-ante* permanent component of risk and the *ex-post* component of shocks. This further decomposition presents some clear advantages over the standard VEU measure. First, it provides a distinct evaluation of the costs of mitigation strategies compared with the coping ones. Second, the permanent component of *ex-ante* risk also captures the impact of risk on mean consumption, via the standard precautionary savings channel, overcoming the main weakness of Ligon & Schechter's (2003) version of VEU. Our extended VEU measure becomes thus fully consistent with the theoretical and empirical prediction that a rational consumer can safeguard against future bad shocks by reducing current consumption and over accumulating saving in safe (unproductive) assets (see Essay 2 and also Caballero 1990, Deaton 1992, Carroll 2001). Unfortunately, we cannot decompose the impact of the *ex-ante* permanent risk on the non-random level of consumption from its impact on risk premium. However, we can test the significance of the two channels by presenting the correlates between our measure of permanent risk and the various components of our vulnerability measure (see section V).

Once we have filtered out both the *ex-ante* and the *ex-post* idiosyncratic components of risk, we leave only the unexplained risk and/or measurement error in the residuals, as follows:

¹⁰For an extensive discussion on how to work out with the original VEU measure after removing the hypothesis of complete markets, please refer to Ligon (2006).

4.4 Model specification and Data

$$\begin{aligned}
V_i = & [U_i(z) - U_i(Ec_{it})] + & (\text{Poverty}) \\
& [U_i(Ec_{it}) - EU_i(E(c_{it}|\mu_k))] + & (\text{trade-related risk}) \\
& [EU_i(E(c_{it}|\mu_k)) - EU_i(E(c_{it}|\mu_k, \mu_t))] + & (\text{Aggregate risk}) \\
& [EU_i(E(c_{it}|\mu_k, \mu_t)) - EU_i(E(c_{it}|\mu_k, \mu_t, s_{\eta it}^2))] + & (\text{Ex-ante idiosyncratic risk}) \\
& [EU_i(E(c_{it}|\mu_k, \mu_t, s_{\eta it}^2)) - EU_i(E(c_{it}|\mu_k, \mu_t, s_{\eta it}^2, x_{it}))] + & (\text{Ex-post idiosyncratic risk}) \\
& [EU_i(E(c_{it}|\mu_k, \mu_t, s_{\eta it}^2, x_{it})) - EU_i(c_{it})] + & (\text{Unexplained risk and measurement error})
\end{aligned}
\tag{4}$$

where $s_{\eta it}^2$ is a latent idiosyncratic term for the *ex-ante* component of risk and x_{it} is a bundle of time variant idiosyncratic households characteristics. Thus, $E(c_{it}|\mu_k, \mu_t, s_{\eta it}^2)$ is the expected value of household consumption conditional on knowledge of *ex-ante* idiosyncratic risk whereas $E(c_{it}|\mu_k, \mu_t, s_{\eta it}^2, x_{it})$ is the expected value of household consumption conditional on knowledge of *ex-ante* risk and a vector of idiosyncratic household characteristics able to capture the heterogeneity in households' exposure and their ability to cope with it. As in Ligon and Schechter (2003), this controls for the idiosyncratic risk component of the vulnerability measure that can be attributed to variation in m observed time-varying household characteristics by filtering it out from the risk component which cannot be explained by these characteristics and from the aggregate and meso variables as well as from all the other components (i.e., the unexplained variance and measurement error in consumption).

Third, we average the VEU outcomes and the value of its risk premia sub-components across the household cohorts belonging to the groups of industries grouped according to their degree of trade exposure and investigate them comparatively.

4.4 Model specification and Data

Model specification

To compute household vulnerability by using our extended VEU measure, we follow a three-step procedure.

First, we choose the utility function and its degree of concavity (i. e., the risk aversion parameter). As for the utility function, in line with Ligon and Schechter (2003), we adopt the Constant Relative Risk Aversion (CRRA) utility function which takes the form:

$$U(c) = \begin{cases} \log(c) & \text{if } \gamma = 1, \\ \frac{c^{1-\gamma}}{1-\gamma} & \text{otherwise.} \end{cases} \quad (5)$$

where γ measures household relative risk aversion (Arrow, 1965; Pratt, 1964). Concerning the risk aversion parameter, estimates of risk aversion in the empirical literature range from 1 (i.e., log utility) to no more than 4 (Lucas, 2003).¹¹ Thus, we carry out our empirical analysis within this range (specifically, from 1 to 3).¹² We also normalise consumption for the poverty lines available for each period, so that for poor household consumption is below 1.

Second, we estimate the unconditional and the conditional expectations of household i consumption included in our vulnerability measure. In the first case, we assume a stationary environment - which is indeed reasonable in our case considering the very short panel - and compute the unconditional expectation of consumption as follows: $Ec_{it} = \frac{1}{T} \sum_{t=1}^T c_{it}$. For the conditional expectations, we assume that the expected consumption expenditure of household i in industrial trade cluster k at time t can be estimated using a linear equation of the conditional log consumption expenditure as follows:

$$E(c_{it} | \mu_k, \mu_t, s_{\eta it}^2, x_{it}) = \alpha_i + \mu_k + \mu_t + \omega s_{\eta it}^2 + \beta x_{it} + v_{it} \quad (6)$$

where $\alpha, \mu_k, \mu_t, \omega, \beta$ are unknown parameters to be estimated: α captures the influence of the fixed household characteristics on predicted consumption; μ_k captures the influence of the (meso) trade-related fixed effects; μ_t captures the remaining effect of common changes in aggregates which are not captured by the meso component (it follows: $\sum \mu_k = 0$); ω is the parameter attached to permanent *ex-ante* risk; and β is a vector of parameters attached to the matrix of household characteristics.¹³ Note that if the latent variables μ_k are

¹¹The common critique to these values is the Mehra and Prescott (1985) “equity premium puzzle”. It shows that if we want to use a stochastic growth model with CRRA preferences to account for the entire return differential between stocks and bonds - historically about 6 percent - as a premium for risk, the parameter γ must be enormous, perhaps 50 or 100 (Lucas, 2003).

¹²According to Ligon and Schechter (2003), we do not expect our results to be very sensitive to the actual choice of γ since we are more interested in investigating the relative importance of the various vulnerability components than its overall magnitude. While in fact the estimates of total vulnerability, poverty and risk are all sensitive to the choice of γ (i.e., to the shape of the utility function), the relative magnitudes of the different components are less sensitive since greater concavity reflects greater welfare losses associated with all the components. We will see that our expectations are confirmed in the empirical analysis.

¹³In order to catch the individual contribution of the m sources of idiosyncratic risks,

4.4 Model specification and Data

jointly significant, then we can reject the null hypothesis of complete aggregate risk sharing across households clustered by trade-related industries.¹⁴ The intuition behind is that this component of risk captures the presence of risk heterogeneity across industries clustered by trade exposure and represents a measure of the different nature of trade risks, and/or the correlated mitigating strategies, relative to the domestic ones. Similarly, if some risk is shared at the aggregate level, then estimates of μ_t will be significant too. The use of a panel fixed effects econometric procedure wipes out further sources of bias due to unobservable household heterogeneity in consumption.

Third, to derive parsimonious information on *ex-ante* risk from our data, we exploit the longitudinal dimension of the panel and derive the variance of innovations in income. The estimated equation, similarly to what has done in many of the previous empirical works (Carroll and Samwick 1997, 1998; Hubbard et al, 1994; Gourinchas and Parker, 2002; Jalan and Ravallion, 2001; Meghir and Pistaferri, 2004; Storesletten et al., 2004) is the following:

$$y_{it} = \delta_i + \gamma_k + \theta_t + \tau z_{it} + u_{it} \quad (8)$$

To filter out the permanent component of *ex-ante* risk, as in Carroll and Samwick (1997) and Krebs et al. (2010), we assume that the stochastic term (i.e., the unpredictable component) of our income equation (u_{it}) is the sum of two unobserved components, a permanent (η_{it}) and a transitory one (ϵ_{it}) that are both white noise and uncorrelated with each other at all leads and lags. We then rely on the intuition that the random walk component in income of each household i implies a linearly increasing income dispersion over time as follows (for additional details on this decomposition, see Appendix 2B in Essay 2):

$$E[\text{var}[\Delta_d y_{it}]] = 2\sigma_\epsilon^2 + d\sigma_\eta^2 \quad (9)$$

we orthogonalise the m variables x_{it} by using a Gram-Schmidt procedure and then rewrite the fourth line of equation 4 as follows:

$$\begin{aligned} & [EU_i(E(c_{it}|\mu_k, \mu_t, s_{\eta it}^2)) - EU_i(E(c_{it}|\mu_k, \mu_t, s_{\eta it}^2, x_{it}))] = \\ & [EU_i(E(c_{it}|\mu_k, \mu_t, s_{\eta it}^2)) - EU_i(E(c_{it}|\mu_k, \mu_t, s_{\eta it}^2, x_{1t}))] + \\ & [EU_i(E(c_{it}|\mu_k, \mu_t, s_{\eta it}^2), x_{1t}) - EU_i(E(c_{it}|\mu_k, \mu_t, s_{\eta it}^2, x_{2t}))] + \dots \\ & [EU_i(E(c_{it}|\mu_k, \mu_t, s_{\eta it}^2), x_{(m-1)t}) - EU_i(E(c_{it}|\mu_k, \mu_t, s_{\eta it}^2, x_{1t} \dots x_{mit}))]. \end{aligned} \quad (7)$$

¹⁴We are of course here excluding any shift in the degree of trade exposure across groups of sectors during the time span of the analysis, which is consistent with the short period of our panel data.

4.4 Model specification and Data

where $\text{var}[\Delta_d y_{it}]$ is the variance of log difference of income of length d for each household in the sample. By using two $\text{var}[\Delta_d y_{it}]$ of different lengths we can estimate the permanent component of the variance of income innovation at the household level as follows:

$$s_{\eta_i}^2 = v_{yid}^2 - v_{yid-1}^2 \quad (10)$$

where $E(s_{\eta_i}^2) = \sigma_{\eta}^2$ and $v_{yid}^2 = \text{var}[\Delta_d y_{it}]$. The latter relies on the assumption of no individual specific growth rates for income (other than those predictable by occupation, education, industry and other personal characteristics).¹⁵

We have already highlighted in section 3 that filtering out the permanent component of *ex-ante* risk lets us also capture the impact of risk on mean consumption via the standard precautionary savings channel, overcoming the main weakness of the Ligon & Schechter's (2003) version of VEU. A second motivation is that according to our econometric specification of the income process, filtering out the permanent component from the stochastic component of consumption leads to unbiased estimates of the *ex-ante* risk (since the transitory component also absorbs measurement errors). A third motivation is that the more persistent the effect of the stochastic component of income is, the larger its impacts are assumed to be (for a thorough analysis of this issue, see Reis, 2009).

Finally, in line with adoption of the CRRA utility function, we assume that poorer households are more responsive to changes in risk. To this end, we again scale up the permanent component of income *ex-ante* risk by the ratio between current household's income and expected lifetime wealth. Our final proxy for *ex-ante* permanent risk for each household i is thus the following:

$$s_{\eta_{it}}^2 = \pi_{it} s_{\eta_i}^2 \quad (11)$$

where $\pi_{it} = (y_{it}/\hat{w}_{it})^n$ and \hat{w}_{it} is our measure of the expected wealth.¹⁶

¹⁵As a robustness check, we run our income equation by also controlling for an additional time trend component in order to capture additional predictable linear unobservable components in the model (which may not be captured by the other predictable components). Unfortunately, we cannot control for this time trend at the household level since $T = 3$ and $\sum(\hat{u}_1 + \hat{u}_2 + \hat{u}_3) = 0$. Hence, we assume that the unobservable components captured by the time trend are homogeneous within each trade category (and additional to those already captured by the trade categories fixed effects). The outcomes of the income equation that includes the linear trend by trade categories as well as the parameters for the fresh consumption equation are reported in Appendix 4B.

¹⁶Due to difficulties in extracting reliable information on the expected wealth from the available observations, we follow Banks et al. (2001) and Giles and Yoo (2007) by replacing expected wealth with an observed level of per capita consumption.

4.4 Model specification and Data

Again as a robustness check, we carry out our empirical analysis for different values of the exponent of the scaling factor (for $n = 1; 2; 3$, consistently with the various estimates of risk aversion parameter).¹⁷ As well as its theoretical foundation, the scaling term has the additional advantage of transforming our “risk term” into a time variant idiosyncratic component as well as introducing explicit heterogeneity to the households’ responses to permanent risk and, hence, heterogeneity in expected mean consumption.

Data

We used panel data for the period 2002-2004-2006 taken from the Vietnam Household Living Standard Surveys (VHLSS). These are nationally representative surveys based on the Population and Housing Census 1999 and developed by the Vietnam General Statistics Office (GSO), jointly with the United Nations Development Programme (UNDP) and the Swedish International Development Agency (SIDA) with technical assistance from the World Bank. In each wave, two questionnaires were filled in, a household questionnaire and a community questionnaire. The first one contained detailed information on household demographic characteristics, education, health and healthcare, income, expenditures, assets and durable goods and accommodation as well as participation in poverty reduction programmes. The community questionnaire gathered information on the demography, health, education and infrastructure of all the rural communities. The VHLSS collected information from a sample of 29,530 households in 2002 of which 4,476 were re-interviewed in 2004 and 2006, out of samples of 9,188 in total in 2004 and 9,189 in 2006. The number of surveyed communes was 2,091 in 2002, 3,063 in 2004 and 3,065 in 2006. Taking into account some inconsistency in the GSO original panel, here we used the Brandt et al. (2009) revised version of VHLSS panel data.¹⁸ Moreover, the following sample restriction was introduced to reduce the influence of unobservables and measurement errors. First of all, we dropped all the households that match the following criteria: i) head of household changed during the panel period and ii) head of household not in the labour force during the entire period. Second, we dropped all the households for which we do not have information on income,

¹⁷According to Skinner (1988) and Guiso et al (1992), the exponent of the scaling factor measures the sensitivity to the level of expected wealth exhibited by the reaction to uncertainty. If the exponent is more than zero, the effect of risk on consumption declines with the household’s resources and the decline is faster the higher the value.

¹⁸As highlighted by Brandt et al. (2009), the GSO original panel data 2002-06 are incorrect: of the 4,476 households interviewed in 2004 that should have a matching household in 2002, 429 have proven to be mismatched (9.6%) and these matching errors in the 2002-2004 VHLSS panel contribute to mismatches in the entire 02-06 VHLSS panel.

4.4 Model specification and Data

consumption and/or assets. Third, to reduce the influence of outliers, we dropped households with per capita income or consumption lower than the first percentile or higher than the last one. Finally, we kept only the households that have observations for the entire panel period as well as real per capita income, consumption and assets other from zero. As a result of these restrictions, the sample decreased to a panel of 988 households.

The variable used for consumption was real per capita food and non-food expenditure in the past 12 months re-adjusted by price indexes of regions and months. Food expenditure included information on both market purchases and consumption from home production of 58 items whereas the non-food expenditure collected information on 32 items such as fabric, clothing, blankets, pillow, tailoring or laundry service, shoes, nylon sheeting, electrical equipment, etc. Poverty lines were expressed in Vietnamese *dongs* as follows: 1,915,000 for 2002; 2,070,000 for 2004; 2,559,000 for 2006.

Lastly, we converted all nominal variables into nationally representative January 2006 prices using three different set of deflators, as suggested by Brandt et al. (2009). Considering that households within each survey are interviewed during different months, the first set were monthly deflators which are needed to convert the income and consumption values to January prices in the respective year. Second, in order to take into account the differences in the cost of living across regions, we used regional deflators.¹⁹ Third, to link January prices of 2002 and 2004 to January 2006, we used the Consumer Price Index (CPI) indicators provided by the GSO, which are 1.279 for 2002 and 1.193 for 2004.

For household per capita income, since the VHLSS do not provide a synthetic measure, we did as follows (for additional information, see also Brandt et al., 2009). We aggregated income into six major categories: income from crops, income from agricultural sidelines, household business income, wage income, gifts and remittances, and other residual sources of income. Income from crops is net income (gross revenue minus current expenditures) from rice; other cereals, vegetables, and annual crops; industrial crops; fruit crops; and crop by-products such as straw, leaves, etc. Agricultural sidelines include livestock and other animal products, agricultural services, forestry services, hunting, trapping, and domesticating wild animals, and aquaculture. Household business income is net income from non-agriculture, non-forestry, and non-aquaculture businesses run by the household and includes the processing of agricultural, forestry and aquaculture products. Wage income includes

¹⁹For the regional deflators, we use the indices provided by the GSO in the VHLSS. We also replicate the same exercise using the different set of regional deflators kindly provided (upon request) by Brian McCaig and the results do not change significantly.

salary or wage payments plus additional payments such as holiday contributions, social insurance payments, etc. for all jobs held by individuals during the past 12 months. Gifts and remittances include payments from both domestic and overseas sources. Finally, “other” residual sources of income include items such as government transfers and earned interest as well as rental income from land and housing.

The set of covariates used in our empirical exercise includes household characteristics (such as characteristics of the head of household head, i.e., linear and quadratic age, marital status, sex; linear and quadratic terms of family size and number of children); education achievements (primary, secondary, upper secondary, technical/vocational, university) as well as village-level infrastructure characteristics (such as the presence of roads, water pipelines, public transports, urban/rural environment). We also include province dummies to control for spatial heterogeneity. As in Essay 3, the classification of industries by trade exposure has been taken from Coello et al. (2010). This is reported in Table 3A-3 in the Appendix in Essay 3. Coello et al. (2010) manually matched the ISIC code of any sector with the SITC classification used in Comtrade and GSO statistics and classified industries as net exporter or net importer according to their trade performance. Non-traded industries are those that cannot be matched with trade data. Crops are classified as export-oriented, import-competing and subsistence crops (non-traded). The main export crops are those that represent the bulk of Vietnam’s agricultural exports, whereas rice is classified as a special category since it is both an export crop and the most important item for self-consumption. The full list of the variables used in the empirical analysis as well as the main descriptive statistics are reported in Tables 4A-1 and 4A-2.

4.5 Empirical results

In this section, we follow the pattern depicted in the previous sections first by predicting expected consumption using eq. 6 and then by estimating the different conditional expectations shown in eq. 4. We thus derive our vulnerability measure and its sub-components. Finally, we present the empirical correlation between our measure of *ex-ante* permanent risk and each vulnerability sub-component.

Since the presence of observed consumption in the scaling term makes it likely that errors in the measurement of this term will be correlated with errors in the measurement of the dependent variable, as in Essay 3, we apply alternative strategies to deal with this issue. As a first strategy, we use one lag of the observed consumption. Table 1 reports the estimated coefficients

of eq. 6. using this strategy.²⁰ Two different specifications are presented and replicated for different values (from one to three) of the exponents of the scaling factor: the first column presents the outcomes with only household and time fixed effects specification²¹; the second column adds the trade-related fixed effects.

It should be noted first that, in both specifications, the covariates are statistically significant and show the expected signs. The signs of age of the head of household and its square coefficients confirm the well-known concave age-consumption profile. Not surprisingly, having children reduces household consumption. The education variables also behave as expected: i.e., higher levels of education actually correspond to higher levels of consumption (although the estimated coefficients are only significant for university education). Urban households, as expected, consume more than rural ones whereas the characteristics of the head of household do not seem to be significant.

Second, the joint significance of the trade-related fixed effects (i.e., groups of households belonging to clusters of industries that are supposed to be characterised by a similar degree of trade exposure), confirms the intuition of the presence of a significant systematic variation in household consumption patterns by trade-related clusters of industries.²² The significance of the aggregate year fixed effects shows that some time variant shocks are shared at the macro level too. Note that the estimated coefficients attached to these fixed effects should be read relative to the benchmark category (non-traded non-food activities and year 2002, respectively, for trade-related and year fixed effects) and, as expected, they are positive by year and negative (with different magnitudes) by trade-related clusters. Due to the joint significance of the trade-related fixed effects, we can argue that the model specification presented in the first columns is mis-specified due to omitted variable bias.

We should take into account that the identification of trade fixed effects in the triple fixed effect specification (i.e., including time, household and trade cluster) applied in the model shown in the second columns is driven by those households that move across trade-related groups. This is because

²⁰It is worth recalling that because of the use of lagged consumption in the scaling factor, the panel is reduced to 1976 observations (i.e., $T=2$)

²¹We assume that the random effects estimators are inconsistent since we cannot rule out the possibility that the heterogeneity terms are correlated with the observables. This implies the inability to identify separately the parameters associated with the set of household observed characteristics which are time-invariant.

²²To preserve these moving patterns across the trade-related industry clusters in the empirical analysis, we do not control for time variant trade-related fixed effects which would be able, in principle, to capture further time variant factors which are contemporaneous to the moving of households across trade-related sectors.

In the fixed effects specification the category "non-traded activities" and year 2002 act, respectively, as the benchmark from trade-related and year fixed effects.

the k trade cluster fixed effects turn out to be zero for any household that does not change trade group over the period under observation (for more details, see Andrews et al., 2006). This identification strategy looks reasonable since the kernel densities of log consumption of both moving and non-moving households look quite similar (see Fig. 4A-1 in the Appendix), whereas the lack of a significant correlation across households between the permanent component of *ex-ante* risk (filtered out from the residuals of the income regression as shown in Eq. 10) and the trade-related fixed effects on consumption supports the assumption of exogeneity of the moving decision with regard to risk (see Table 4A-6 in the Appendix). Hence, our identification strategy based on moving households does not seem to be affected by any significant bias. For a closer look into how many households move from one trade group to another over the course of the panel and what the origin and destination trade groups are, see Tables 4A-3 and 4A-4 in Appendix 4A. Specifically, Tab. 4A-3 derives the number of moving households by trade categories by decomposing the between and within variation of the panel. The between variation looks at the variation across households whereas the within variation indicates the percentage of households that are always in the reference trade category. In practice, when looking at a specific trade category, the between variation tells us how many households have been in that trade category at least once, whereas the within variation tells us how many of these households have always been in that trade category (the latter is a measure of stability of the trade-related status). For example, focusing on “exporting industries”, the table shows that 78 households have ever been in that category over the course of the panel (7.89% of the 988 total households in the panel). This figure includes 47 households that have always been in that category (i.e., 60.26% of the 78 households that have ever been in this specific trade category). This means that 31 households out of 78 (3.14% of the total households in the sample) have not always been in the same trade category over the course of the panel. Looking at all trade categories, the table confirms that, notwithstanding some heterogeneity across groups, 496 households in the panel actually move across trade-related categories over the course of the panel (i.e., 50.2% of the 988 total households in the panel). Another way to look at the issue is to compute the between total percentage for the entire panel time frame (i.e., the fraction of total households that have ever been in one of the possible trade categories: $[1484/988] * 100 = 150.2\%$). This confirms that 50.2% of the households have been counted more than once because they actually moved across groups. Tab. 4A-4 shows the details of the transition matrices by trade group of origin and trade group of destination (i.e., the frequencies and associated percentages of households that moved across trade categories over the periods 2002-2004 and 2004-2006).

Specifically, the frequencies (and associated percentages) of the households that changed trade categories from one survey to another for both periods are those that lie off the diagonal of the respective transition matrix.

Third, as expected, the *ex-ante* permanent component of risk is significantly and negatively correlated with household consumption. This also shows the consistency of our empirical exercise with the theoretical prediction of precautionary saving behaviour under risk. In other words, our consumption estimates confirm that Vietnamese households register, generally speaking, a lower path of consumption because of *ex-ante* risk (as a function of mitigating strategies) even when they do not experience any shock. In line with the outcomes in Essay 2, the overall loss due to permanent risk is tiny but statistically significant (about 0.03% of annual real per capita consumption for the average consumer characterised by a concave utility function).

To be consistent with the outcomes in Essay 3, even if in this case the adopted panel fixed effect specification softens the risk of residual endogeneity, we report in Table 2 the outcomes of the same estimates where in the scaling factor we proxy household wealth with the same index of house characteristics and land physical availability applied in Essay 3. It is useful to recall that this is derived by applying principal component analysis to available VHLSS data and is not influenced by monetary terms. Table 2 shows that the permanent risk coefficients in this case decline both in magnitude and significance. However, it is apparent that the negative relation is still significant when we assume that the poorer households are characterised by a higher degree of concavity of the utility function (i.e., when we adopt the square of the scaling factor in the estimates). It is worth noting that, also in this case, we face a slight reduction in the number of observations because of the availability of data for the variables included in the index (see Tables 4A-1 and 4A-2 in Appendix 4A). As largely expected, the magnitude of the phenomenon actually decreases along with the number of additional controls to soften endogeneity in the estimates. Since we are working with a very short panel a prudent interpretation is to see the difference between the coefficients in Table 1 and Table 2 as upper bounds and lower bounds, respectively, of the true parameters.

As a further robustness check, we also run another income equation by controlling for an additional time trend component by trade categories in order to capture additional predictable linear unobservable components in the model (which may not be captured by the existing ones). The outcomes of the income equation that includes the linear trend by trade categories as well as the parameters for the fresh consumption equation are reported in Appendix 4B. As can be seen from Table 4B-2, whereas the outcomes are of course different in detail, the parameters for the consumption equation

4.5 Empirical results

In the fixed effects specification the category "non-traded activities" and year 2002 act, respectively, as the benchmark from trade-related and year fixed effects.

are consistent with those in Tables 1 and 2. The relationship between expected consumption and the permanent risk components (computed using the new set of income residuals) is still negative and statistically significant (even if smaller in magnitude). It is worth noting that the presence of the additional time trend component actually reduces both the magnitude and significance of the coefficients associated with the observed characteristics in the income equation (see Table 4B-1), highlighting that our preferred specification (without time trend) does not leave out relevant non-random trends in income that inflate our permanent proxy for income risk.

Table 3 reports the outcomes of the various components of our vulnerability measure (Eq.4) by column both for the overall sample and for the subsample of households classified as vulnerable (about 20% of the sample). The first three columns in Table 3 show overall vulnerability, in utils, as well as the relative weights of its poverty and risk components. Of course, if we look at the entire sample, the average level of vulnerability is negative and so is its poverty-induced component, while all the components are positive if we select only the sub-sample of households classified as vulnerable. Note that the risk-induced vulnerability sub-components (trade-related included, see section 3) are, on average, positive for all sampled households. It also demonstrates that the households not classified as vulnerable show, on average, positive risk-induced vulnerability.

Again for sensitivity purposes, we present the vulnerability outcomes for different values of the CRRA utility derived for different levels of the risk aversion parameter ($\gamma = 1; 2; 3$). Total vulnerability is the sum of risk-induced and poverty components. As expected, if we increase our risk aversion parameter, the vulnerability estimates also increase in magnitude, but the relative pattern across its components does not change much. For instance, “risk-induced” vulnerability (reported in the “overall risk” column in Table 2) actually doubles for the entire sample (from 3% to 6% of overall vulnerability) and becomes more than five times larger for vulnerable households (from 3% to 16%), but its relative contribution on overall vulnerability does not change. Acknowledging that the overall risk-induced component includes both unexplained risk and measurement error, the columns from four to eight report the further decomposition of overall risk proposed in Eq.4. The fourth column shows the meso (trade-related) component of overall risk-induced vulnerability, cleaned by unobservables and measurement errors. It turns out to be the main component of risk-induced vulnerability, on average, for all sampled households ranging from 4% to 12% (and from 6% to 49% for vulnerable households). This confirms our intuition that trade-related risks (i.e., risks that are not fully shared across households clustered by trade-related industries) matter in determining household risk-induced

vulnerability. The fifth column filters out the component of truly covariate shocks. The sixth column isolates the component of vulnerability due to the ex-ante permanent risk. It shows once again that the relative weight of the ex-ante risk component is low compared with the others (even if we are here assuming this to be a lower bound of the possible true influence of this component in vulnerability analysis). The seventh column refers to the ex-post idiosyncratic components of risk. The last one is the residual unexplained sub-component. All these sub-components sum together to form the overall risk component.

Fig.1 provides a breakdown of the sub-components of the VEU overall risk component for the sub-sample of households classified as vulnerable (for the sake of brevity, only when $\gamma = 2$). It is clear from Fig.1 that the risk-sharing deviations by categories of households classified by trade exposure are significant and, in some cases (e.g., exporting industries, rice, other export crops, and import competing crops), represent the most significant component. Fig.2 reports the same statistics, but is computed by reversing the order of the decomposition of the VEU overall risk between aggregate/covariate risk and risk by trade groups (i.e., assuming deviations from risk sharing by trade categories to be a residual subcomponent of the VEU overall risk component). Table 4A-7 in Appendix 4A shows the full statistics. As largely expected, in the latter case, the relative weight of the risk-sharing deviations by trade categories is greatly reduced and is no longer the most significant component. However, also in this case, the sub-component of risk-sharing deviations by trade categories is different from zero, in line with the statistical significance of the fixed effects by trade categories in Tables 1 and 2. This exercise highlights the need to include a trade meso component of risk in VEU.

Unfortunately, we cannot assess the separate impacts of the *ex-ante* permanent risk on the poverty and the risk components of vulnerability. We can only test for the presence of possible correlations between the *ex-ante* permanent risk and the various components of VEU. To test this we also relax the assumption of homogeneity across the conditional distribution of vulnerability by applying a quantile regression framework.²³ Fig. 3 plots the values of the quantile estimated coefficients of the relationship between the *ex-ante* permanent risk and the various components of our extended vulnerability measure for each 5% of vulnerability distribution (reported on the

²³The quantile approach assumes that the conditional distribution of the dependent variable is not homogeneous across households. It applies a linear programming approach to obtaining the coefficient estimates which does not involve simply running a set of separate OLS regressions. It is worth noting that the precision of the estimates is dependent on the density of the points in each quantile.

4.5 Empirical results

Figure 1: Comparison between the sub-components of the VEU overall risk by clusters of households computed as in Eq.3 (vulnerable households)

horizontal axis) across all the sampled households (for the sake of brevity, also in this case, only the estimates for $\gamma = 2$ have been shown in the figure. The outcomes of the regressions for the 25th, 50th and 75th percentiles of vulnerability distribution for different values of the γ parameters are reported in Tabs. 4A-8, 4A-9 and 4A-10 in the Appendix).

The OLS (mean) regression coefficients are also reported in the graphs (represented by the dashed line) as well as the confidence intervals both for the quantile regressions (represented by the grey areas) and the OLS ones (represented by the lighter dotted lines). Even if based on different scales, the graphs clearly show that the *ex-ante* permanent risk correlates with vulnerability both via its poverty-induced and its risk-induced components (see the first three graphs reported in the first row of Fig. 3). Within the risk components (see the graphs in the second row), there is, on average, a negative correlation with aggregate vulnerability (the mean regression coefficient is negative) and a positive correlation with trade-related vulnerability and idiosyncratic vulnerability. The main feature of Fig. 3 is, however, that the relative impact of the *ex-ante* permanent risk actually increases moving up across different quantiles of vulnerability distribution (with the most vulnerable households being the most severely affected). This pattern is confirmed, with some degree of heterogeneity, for all the sub-components in our extended

Figure 2: Comparison between the sub-components of the VEU overall risk by clusters of households computed reversing the order in Eq.3 (vulnerable households)

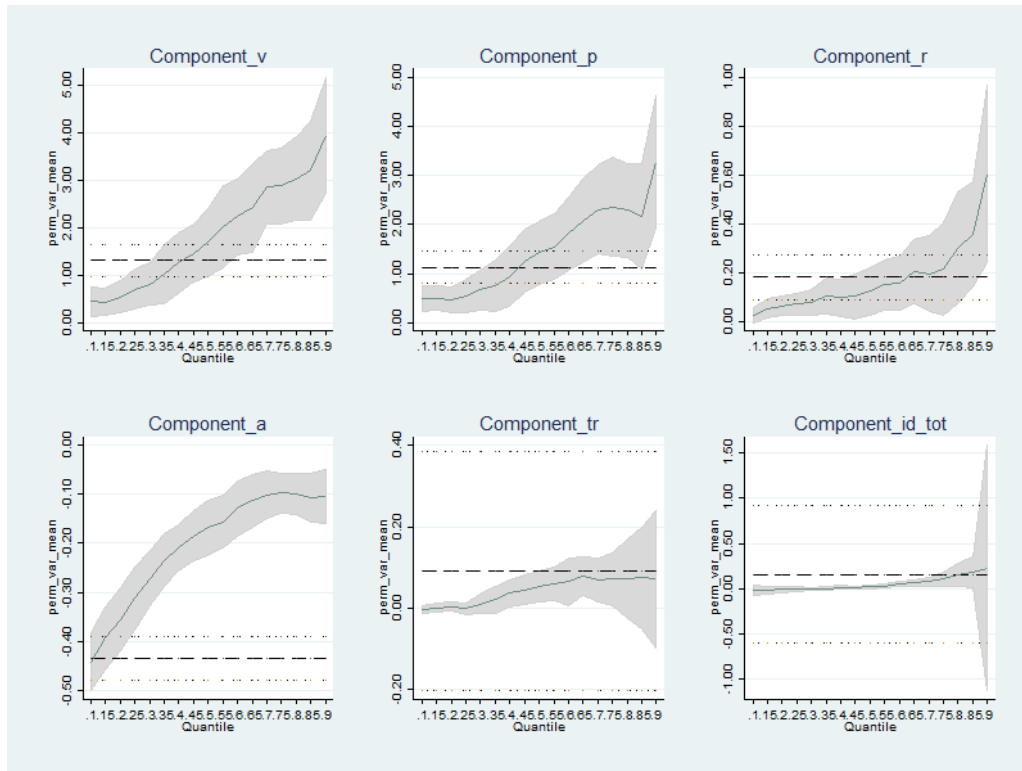

vulnerability measure. Note that in this case, running a simple OLS, which assumes homogeneity in the conditional distribution of vulnerability, would underestimate the relationship between *ex-ante* risk and the aggregate component of vulnerability and overestimate the relation with the trade-related and idiosyncratic components, respectively.

4.6 Conclusions

This paper addresses the timely issue of trade-induced vulnerability using the Vietnam Household Living Standard Survey (VHLSS) panel data for the period 2002-2004-2006. The added value of this exercise stands in proposing an extended version of the VEU measure of vulnerability that is able to address the presence of trade-related heterogeneity in households' exposure to risk more appropriately and overcome the most common weaknesses of current available measures of vulnerability. More specifically, we present a method of decomposing the impact on vulnerability of the *ex-ante* risk and its correlated risk-mitigating strategies from the *ex-post* ones and looking separately at the relationship between *ex-ante* risk, risk premium and mean consumption. Our empirical results reveal a number of useful insights for

4.6 Conclusions

Figure 3: Permanent risk correlates with VEU components by quantiles of the households' vulnerability distribution

Legend:
v=vulnerability; p=poverty induced; r=risk induced;
a= aggregate risk; tr=trade-related risk; id=idiosyncratic risk

policymaking: first, the risk-induced component of vulnerability consistently matters in determining households' overall vulnerability and second, the presence of a relative inability, on average, to share risks across households involved in different trade-related clusters. This confirms our intuition that trade-related risks (i.e., risks that are not fully shared across trade-related industries) matter in determining household overall vulnerability. Third, we show that the *ex-ante* permanent risk is significantly correlated with both poverty, via the precautionary saving channel, and all the subcomponents of the risk components of vulnerability (trade-related included). Fourth, we show that the relative impact of the *ex-ante* permanent risk actually increases along with the increase in the upper percentiles of vulnerability distribution (with the most vulnerable households being the most severely affected).

In the fixed effects specification the category "non-traded activities" and year 2002 act, respectively, as the benchmark from trade-related and year fixed effects.

Conclusions

Although each essay focuses on a specific issue, by putting them together, this thesis provides a thorough understanding of trade-induced vulnerability, both conceptually and empirically. Moreover, in all the reported empirical analyses - except those with cross-sectional data (Essay 3) - we are able to isolate a clean measure of the ex-ante permanent risk, by filtering out possible measurement errors using Carroll and Samwick's (1997) decomposition, as well as to control for possible additional endogeneity in the model by using panel fixed effects (Essay 4) and system-GMM estimation techniques (Essay 2). In this respect, Essay 3 is an exception. It is a first effort to present a comprehensive analysis of vulnerability under *Doi Moi* by exploiting the full set of available rounds of household surveys currently available. While the lack of panel data makes it impossible to rule out the influence of unobservables, this effort represents, in my opinion, a fruitful way to address the issue, conceptually. Since we are facing a chronic lack of panel data in developing contexts and market failures hamper the actual predictability of simulation exercises, I believe that deriving insights from available cross-sectional data, taking explicitly into account the problems of observability without the availability of panels, actually represents an opportunity that should not be missed. It would be at least as fruitful as investing in the creation of additional panel data at the household level.

The review of the literature in Essay 1 clearly shows that trade openness could in principle magnify risk, impact on households' optimal portfolios, and lead to net welfare effects that are less positive than expected in the long run. As a result, households in the midst of trade reforms may employ strategies to mitigate risks and reduce welfare variability. For instance, households may try to reduce the variability of their welfare by relying on income diversification (i.e., combining activities with low positive covariance), income skewing (i.e., allocating resources to low-risk and low-return activities), asset smoothing, strategic migration, etc. (Dercon, 2005). These actions can result in deviations from a smoothing path of consumption (and saving) behaviour and/or imply, especially for the poor, conservative choices that lower

the expected value of income (and consumption) in exchange for lower variability. Hence, these strategies can be costly in the short run (Coate and Ravallion, 1993; Udry, 1994; Townsend, 1994, 1995; Besley, 1995; Morduch, 2002; Elbers and Gunning, 2007; Giles and Yoo, 2007; Jalan and Ravallion, 2001) with negative permanent effects also in the long-run (Ravallion 1988; Morduch 1994; Dercon, 2005). Consequently, any measure of trade-induced vulnerability which is not able to take adequately into account the risk-induced component of “*ex-ante*” changes in behaviour is biased downwards. For example, households in the midst of a trade reform may deviate from consumption smoothing to safeguard against unexpected future bad shocks by carrying out “extra saving” (shying away from profitable but risky investments) and/or by self-imposed reluctance to borrow (Carroll, 2001, Caballero, 1990, Deaton, 1992) with permanent effects on their welfare. This is the innermost source of vulnerability since it is neither directly observable nor linked to an actual manifestation of shocks.

Essay 2 builds on this intuition using a long cross-country panel data set. It highlights a significant cross-country association, on average and *ceteris paribus*, between *ex-ante* permanent risk and deviations from consumption smoothing, resulting in a significant amount of extra-saving and lower consumption prospects. It shows that this is particularly evident in the most recent decades and holds across the entire income distribution. The conclusion argues that standard certainty equivalent analyses that do not control for the precautionary saving component can be affected by omitted variable bias and underestimate risk. On the other hand, it also shows that these empirical results ultimately confirm the Lucas’s (1987) intuition regarding the low value of stabilisation policies.

Consistent empirical evidence is derived in Essay 3 by relaxing the representative agent assumption and taking advantage of the availability of several rounds of household living standard survey data (VLSS and VHLSS, covering a period between 1992 and 2008). Even if, as already stated, this empirical exercise cannot be considered a proper test of the precautionary saving theory because of its static nature, these results are consistent with the provisions made by theory, i.e., that *ex-ante* risk implies a lower level of current consumption. The inconsistency of alternative interpretations of these results is apparent: why should both the unobservable heterogeneity and measurement error change according to household trade exposure across sectors? And why are households working in the more exposed trading sector more, and increasingly, severely affected by unobservables and measurement errors than households working in the less trade-exposed sector? And, even more so, why should the impact of unobservables and measurement errors on consumption behaviour be negative? To provide explanations, we need to as-

sume that the households that self-select to participate in the more exposed trade sectors present a set of common characteristics, unobserved to the researcher, or alternatively a common path in their relative measurement error, that have a negative impact on their consumption behaviour. Even if these assumptions are correct, the empirical result would still be a very relevant issue for policymaking and would imply a partial revision of the assumed trade benefits for the welfare of Vietnamese households working in the most exposed trading sector. As a matter of fact, the nature of the heterogeneity of the *ex-ante* income innovation on trade-related sectors as well as the role of risk management strategies actually engaged in by Vietnamese households need more careful investigation.

Essay 4 applies the same empirical exercise to the available set of panel data (at the expense of reducing the time span of the analysis) and presents an extended version of Ligon and Schechter's (2003) measure of vulnerability as low expected utility in order to isolate the trade component of vulnerability. This shows more robust empirical outcomes: first, risk-induced vulnerability consistently matters in determining the overall vulnerability of households and second, the relative inability, on average, to share risks across households involved in different trade-related clusters. This confirms the intuition that trade-related risks (i.e., risks that are not fully shared across trade-related industries) matter in determining household overall vulnerability. Third, it shows that *ex-ante* permanent risk is significantly correlated with both poverty, via the precautionary saving channel, and all the sub-elements of the risk components of vulnerability (trade-related included). Fourth, it shows that the relative impact of *ex-ante* permanent risk actually increases as vulnerability distribution increases (with the most vulnerable households being the most severely affected).

The main contribution of this work has been to provide a set of useful insights to reconcile, conceptually and empirically, the theory of precautionary saving with an empirical analysis of vulnerability, that have been considered to date as two separate issues (current vulnerability measures continue to use average consumption as the risk-free counterfactual). Second, it demonstrates, empirically, that household consumption behaviour is sensitive to permanent risk and that this empirical evidence holds both in a long-term (pre-crisis) cross-country (see Essay 2) scenario and in a within-country context (see Essays 3 and 4). Third, it shows different workable methods of complementing current standard vulnerability measures with an analysis of trade-related risks (taking advantage of empirical evidence of the absence of full risk sharing across households clustered in different trading industries). Finally, it detects empirically significant differences in household vulnerability showing that the relative impact of the *ex-ante* permanent risk (included

its trade-related component) actually increases as vulnerability distribution increases (with the most vulnerable households being the most severely affected).

This research has strong policy implications. First of all, by demonstrating that the characteristics of the vulnerable differ significantly from those of the poor, it shows that targeting only the latter means that we exclude a significant group of households that are at risk of a decline in living standards. Moreover, it challenges the widespread idea that the poor will be among the most vulnerable people (World Bank, 2000; Calvo & Dercon, 2007a). Empirical analyses show that: i) shocks occur everywhere across the income distribution and affect the poor and non-poor alike (Tesliuc and Lindert, 2004); ii) the poor can show a higher degree of resilience even if they rely on coping strategies that could damage their growth prospects (Jalan & Ravallion, 1999, Zimmerman & Carter, 2003; Carter & Barrett, 2006; Carter & al., 2007). This illustrates a key difference between resilience and responsiveness that is also worth bearing in mind when drawing policy implications. Second, it demonstrates that output volatility does not translate one for one to consumption volatility and that *ex-ante* permanent risk is significantly correlated with both poverty, via the precautionary saving channel, and all the subcomponents of the risk components of vulnerability. Finally, it shows that risk-induced vulnerability consistently matters in determining households' overall vulnerability and, specifically, that trade-related risks (i.e., risks that are not fully shared across trade-related industries) also matter in determining household overall vulnerability.

To the best of my knowledge, this is the first conceptualisation, supported by thorough empirical assessments, of the influence of trade-related risks on household vulnerability. Although it does not represent, by any means, an argument against free trade, it is a necessary quest to deepen our knowledge of the stabilisation needs linked to trade reforms ranging from the promotion of credible stabilisation policies (e.g., reducing price fluctuations) to the design of new insurance schemes that target vulnerable households (e.g., raise the creditworthiness of small farmers' participation in export cropping). As a result, this work clearly improves our capacity to assess the "vulnerability hazard" of trade reforms, at different levels of analysis. While an evaluation of the impact of covariate risks induced by trade openness is of major interest to international economic policy, an assessment of trade-related idiosyncratic risks will help national policymakers to set priorities and calibrate domestic mitigation strategies and safety nets. The empirical evidence of the persistence of a significant presence of risk-induced vulnerable households in Vietnam during *Doi Moi*, combined with the inability to share risks by households clustered in different trade-related groups of activities, should

inform national policy in terms of safety nets. In this respect, it has to be stressed once more that trade-induced vulnerability is not directly observable or linked to the actual manifestation of shocks.

While informative and comprehensive, this piece of work prepares the ground for a number of additional research questions. First, Essays 1, 3 and 4 highlight the significance and relevance of the “meso” dimension of vulnerability. At present, this appears to be one of the most promising paths towards empirical evidence of trade-induced vulnerability at the household level thanks to the robust empirical evidence of heterogeneity in risk exposure by trading industries. What actually drives this heterogeneity (heterogeneity in risk-mitigating strategies and/or in the inherent exposure to different kinds of foreign risks) is something that needs additional careful investigation. Second, Essay 4 presents a first attempt to provide an extended version of VEU. The primary scope of this piece of work was to amend it to filter out a “meso trade-related” component of permanent risk. It incidentally also dealt with the main weakness of the VEU measure related to the inability to take full account of precautionary saving behaviour. While this essay presents a first insight into this issue by filtering out the *ex-ante* risk from *ex-post* shock within the VEU measure, additional efforts should be made to provide a causal analysis of their relative influence on the separate poverty and risk-induced VEU components.
